In 1885 I saw a young man who had been refused at an insurance office for an irregular heart. He was brought to me by his own medical man in consequence, and I certainly could not in that instance find fault with the decision, for his heart was tumbling about in a most extraordinary fashion for a man, and such as I have rarely seen in that sex and at that age before or since. I cannot go at length into my reasons for regarding the affection as a functional one; it must suffice to say that the shape of his head, his whole bearing, and the previous history, given me by the gentleman who brought him, who was an old friend of his as well as adviser, showed conclusively that he was an extreme neurotic. He wanted to get insured before he went abroad, and he was obliged to start in some ten days or so. I told him that I was convinced that there was no disease of his heart, but as to getting insured before he went, that was impossible, as it was clear that no examiner would look at him with his heart in that state, and it was little likely to quiet down with an ordeal such as that before him under the circumstances of the hurry. So I advised him to go abroad, and as his refusal had much upset him, to go to some medical man near him, and to have his heart examined frequently, thinking that when he got used to the process he would soon be reported upon more favourably than we could do at that time. My expectations were quite justified, for after some months I heard from him, saying that he had got his life insured, and that now his mind was at rest. I do not think that in the end he had any desire for the insurance as an investment, but merely because it gave him a certificate of the soundness of his heart. He comes to England periodically, and I have seen him several times in the course of the six years that have now elapsed since my first introduction to him, and he has hardly put his foot on shore before he rushes off to me to get his mind set at rest. And here is the point that makes me a little uneasy about him: he has several times had recurrences of extreme irregularity of the heart's action, generally after mental worry, and once in this state I sent him to Homburg, and some one who saw him there, not knowing so much as I did about him, shook his head at him, kept him on one floor, made him go about in a Bath chair, and sent him home again more dead than alive from sheer fright. But although I judge the nature of the case to be a neurosis, I cannot but fear that as he advances in years a muscle or nerves of such irritability may fail under the stress of even ordinary existence, and that he may not live out his term. And yet, on the other hand, the case is much like, in all but the sex, the palpitation that is so common in women, and which does not, so far as I know, do much, if anything, to shorten life. Nay more, it is a condition that may well excite astonishment by the small amount of disturbance that it creates. There may be some amount of discomfort, but even that is difficult to speak of accurately, for going with the disturbed cardiac action there is so much nervous erethism that it is uncertain how much of the distress is due to the one and how much to the other; and how little of anything there may be sometimes is well impressed on my mind by the remembrance of a lady who walked into my room a year or two ago after a morning's shopping in Regent-street, saying that she had had a palpitation all that night and morning, and would I please to give her something to stop it. I found her heart beating 160 per minute, and I do not doubt that it had been doing so through all her peregrinations in the shops of the West-end.

Then, again, there are other cases that seem to suggest that neurotic disturbances may lead to actual organic disease. I saw this case the other day. A man of about forty-four—so far as is known in perfect health at the time; in fact, he was passed first-class for insurance just before he left—went out to the colonies to assume a very important and anxious financial post. Before he went he had been in the habit of taking a good deal of exercise, and his new berth kept him so continuously occupied that he had not only no time, but neither had he the energy or the inclination for it. His work told upon him severely, and he felt that it did so, and within six months of his taking up his new post he found himself so short of breath that he was obliged to seek medical advice. He was found to have mitral incompetence, and he has had it ever since; and, what is more, he was, so long as he remained at his post, slowly going downhill, until he relinquished it and started for home. Since that time he has, according to his own account, continuously improved. It seems quite possible that the fault here may have been a primarily nervous one; that the man's whole energy was used up by his brain work, and that for the want of its supply the heart muscle dilated, and led to the mitral incompetence at the same time that the body muscles were disinclined and incompetent for their wonted exercise. But of course it cannot be denied that there is, at any rate, another explanation; for the heart that is accustomed to work, as is that of a man who makes it his business to take a good deal of exercise, when thrown into idleness, as it is in great measure when its master changes all his habits of life and betakes himself to a very sedentary occupation, is very likely to grow indolent, and it is the indolent hearts as much as the overworked ones that dilate. As a further point in reference to the influence of nervous failure in producing organic disease, I would add that I have seen one or two cases, though they are happily rare, where, without any definite disease, yet with some permanent sense of discomfort about the heart, a patient suddenly falls down dead, and all that is found post mortem is a dilated heart. Again, it cannot be said that such cases have any certain connexion with any definite nervous cause, but in the one or two cases that I have seen there was a something about the individuals that led me to class them as belonging to the group of the neurotic.

Now this subject leads me on to another that has similar risks—viz., Graves' disease. I have already said that I regard this disease in what may be called its fully developed form as one that shades off in all directions into conditions that are not generally considered in relation with it, but which ought to be so considered, in my opinion. Just now the exophthalmos and the thyroidal enlargement are somewhat at a discount, and we hear more of muscular tremors and some other local phenomena; but what has long struck me is that the central feature

Digitized by Google

of all these cases is, without any exception, their extreme nervousness. I hope no one will take exception to my making use of this popular term, but it is really an exceedingly useful one. And what do I mean by it? Well, I understand a state of the central nervous system in which the persons start suddenly at the least unexpected noise; in which the least excitement makes them tremble all over or flush, or break out into a perspiration; in which an impulsive word or a sudden act will send their heart into a state of palpitation; they are in a perpetual state of that common and happily temporary one of a nervous man who is about to make his first speech: his tongue gets dry and sticks to the roof of his mouth, his neck swells, and he feels uncomfortable in his respiration; his heart is beating so fast that it would seem that it must stop; and his head throbs so badly that if the memory of pain were not short-lived he would never trouble an audience again. But in this picture of Graves' disease it is not the muscular tremor that is the essential feature; it is not the enlargement of the thyroid that is either, or the protruding eyeballs; all of them are included in the still more fundamental state of decrepit control on the part of the centres, and, whatever it be, it lies deep in them. So that when I see, as one so often does see, a nervous woman or man with a very rapid heart, or excessive pulsation in the neck or abdomen, with undue tendency to sudden sweats, with a want of muscular control, as evidenced by tremor and so on, I see in each of these, outlying symptoms of the condition, whatever it be, that causes the assemblage of symptoms we call "Graves' disease," and which seems to me most aptly likened to a state of permanent blushing of the centres involved. I should like, however, to remark that such symptoms are common to many forms of nervous breakdown. For instance, many of them are found in chronic alcoholism, they are seen in some cases of melancholia, in the decrepit state engendered by overwork, by excesses of any kind; sometimes they occur with glycosuria, and no doubt in many other conditions also. And herein is another point of interest, if I may judge by my own experience—viz., that all these conditions, more or less, are benefited by the same drug—opium. I believe for patients suffering from Graves' disease there are no remedies comparable to the rest and absolute freedom from fussing that are to be procured in a hospital, and there is no drug that does them so much good as small doses of opium, combined with strychnia, cod-liver oil, and all remedies that go to build up the nervous centres.

I can only mention one other condition that has to do with the question of weak hearts—viz., faintings that are supposed to own a cause of this kind. They are excessively common; far more common in women than in men, and they come for an opinion in numbers because the uninstructed associate the condition of fainting with disease of the circulatory centre. Now, except occasionally in old people, is it ever so? If it be, I confidently assert that it is a very rare occurrence; and for myself I can say that of the large number of cases of this kind that have come under my notice, and of which I have notes, in no single instance have I been able to discover any organic disease, and in all there has been ample evidence that they were nerve cases and not heart cases. I need hardly say that faints are often of an epileptic character. I do not wish to assert that all these cases are of that nature, but short of epilepsy there are many conditions that emanate from the nervous system and lead to faints that are altogether outside the heart. The sort of case met with is after this wise. A gentleman aged thirty-three, who has been in the tropics for some years, and has had malaria and rheumatic fever, has had within a short time of returning home two attacks of palpitation, in one of which he fainted for a minute. He has had one slight attack since he came home. He came to me because he thought his heart was affected, but there was nothing discoverable, and as he was very tremulous and nervous I believe it was all brain. Another interesting case of this sort I saw down in the country some three years ago. A lady, aged twenty-eight, had been somewhat recently confined and was anæmic. For some days before I saw her she had been going off into repeated faints, and had kept the whole house in a perpetual panic. I do not know how many nights the doctor had slept in the house to see an attack, but his presence always seemed to keep them off, and he had never see none. The patient was a light-haired, lively, neurotic Irishwoman, subject to vertigo, but with no organic disease of any kind. And yet one more, also in a lady of the same age (twenty-eight), who has been subject to attacks of giddiness for years, but who of late has had most curious seizures that come on quite suddenly while she is walking about. She has all the feeling that she may faint, but never goes quite off; sometimes she goes pale, but more usually she flushes and gets into a perspiration. At the onset of the attacks her heart seems to stand still for a second, and then off it goes into a violent palpitation. The heart sounds were a little irritable, but there was no evidence of organic disease. Of course these cases do not touch the question of fainting in organic disease of the heart, though even there I think it may be said that it is a much rarer thing than is supposed. I remember having a patient of this sort under my care in Guy's Hospital some years ago, and kept him in for some time because the case was so very uncommon in this respect, but even there I was in doubt. He had definite mitral or aortic disease, I forget for the moment which, and he used to have faints; but I believe in that case the heart disease led in some way to an epileptic attack, and that it was not a state of simple syncope. People with dilated hearts may die suddenly from syncope; old people with degenerate muscle may die in like manner, but the fact remains that those who are subject to faintings are very seldom sufferers from heart disease, and it is also the outcome of clinical experience that faints of this kind are not dangerous, and need never excite much alarm for the immediate issue. Practically they occur in boys and girls and women, and are a symptom of a deranged or weak nervous system.

And now let us pass for a few minutes to peripheral disturbances, which, although we do not know much about their pathology, would yet appear to be largely neuro-vascular in their development; "vaso-motor" they are more usually called, but as I am more concerned with central causes than with local, I shall look at the affections concerned more especially from that point of view. We have heard a good deal of recent years of what has been called "Raynaud's disease"—a gangrene of more or less of the extreme periphery, whether it be of the tips of the fingers or of the toes, or of the rims of the ears. This typical or extreme form of Raynaud's disease is decidedly uncommon; but inasmuch as I do not see where to draw the line between this severe disease and a number of slighter grades, it seems to me to be a very common affection. For instance, a lady came to me this morning with some rather pronounced irregularity of her heart, and the symptom she made most of, thinking it to be an important one in relation to the heart disease she supposed she had, was that she always had cold feet. "Madam," said I, "you know the old saying, 'A cold hand and warm heart,' and if you remember that *heart* should be rendered soul or spirit, cold hand or foot means an active brain. It is never a symptom of heart disease. 'It is a good sign to have one's feet grow cold when he is writing,' says the Autocrat of the Breakfast Table." This seems to me the very mildest form of Raynaud's disease; so mild indeed that is no disease at all. And of other mild conditions that are of the same kind I would mention the thin skin and blue hands, sometimes a little swollen, that are seen quite commonly in young women, and sometimes also in children. Closely allied to these is the proclivity to chilblains; and then there are the peculiar waxy or corpse-like fingers, that are described as dead fingers. There are, besides, a number of less well-defined conditions of disturbed sensation—pain in some, numbness in others—which go to complete the picture of the disease. Now all these things are at first sight purely local, and it is of course quite possible that in the future a local pathological process may be assigned to them; but for the present the local changes are of no use to us, we cannot treat them locally, and the far more important point for recognition is that they occur in people of a certain temperament. Herein is shown one of the great difficulties of my subject, for these several manifestations that I have named probably do not occur in the same kind of person; the livid blue hands and the tendencies to chilblains occur in the lethargic neurotic, and in those in whom one may surmise that the play of nerve force is always at a low ebb, the neurosis being one of initial default. In those whose fingers die it is certainly not always so, and I think that it is more the affection of the quick-brained and vivacious. This brings me to remark, as I have not hitherto done, on the wide field occupied by the neurotic temperament. It is seen, indeed, in all sorts and conditions of mental activity—in the most logical, in the

Digitized by Google

most impulsive, in the most emotional as well as the most unsympathetic and cold, in the strong minded as well as in those who are wanting in resolution. But all these milder forms of Raynaud's disease are found in those who are of this constitution, and the disease must be treated, not by attacking the local change, but by devoting attention to the general vigour of the system. Improve that and you will do something to better the local distress, though one cannot say that the measure of success is any great thing to boast of, or leaves us with nothing to be desired. I have said that such and such symptoms make up the picture of Raynaud's disease, but I am not sure that its connexions are not wider even than I have here indicated, for I have in my mind the case of a little child who has had for a period of many months a curious bullous eruption, that seems to be certainly due to some neurotic disturbance, for it comes on after any little over-excitement. And when I think of this case there are several conditions of the skin, notably pemphigus and its curious control, not cure, by arsenic, various pruriginous conditions, and even such pronounced conditions as psoriasis also, that are by no means without their interest in this regard. Psoriasis particularly is a disease of the neurotic; and had I time there are one or two cases from my note-books where it and distributed joint lesions have gone with general nerve tremor, such as indicated serious nervous failure, while in a few others the disease has been associated with mental failure such as threatened actual madness. One cannot, however, fail to remark that psoriasis in one respect is an exception to the rule I am preaching; for it is a disease that is best treated by local remedies.

But I must leave these questions to say a few words upon angina pectoris, a more important because more terrible disease. And I would repeat here what I said at first, that it is a little off the lines of my present theme, because, although I believe it to be a neurosis in some cases, it is nevertheless a neurosis that cannot be treated on general principles, nor can it be said that it occurs in those of a neurotic temperament to any marked extent. There was a discussion a few months ago at the Medical Society on this subject of angina pectoris, but what I have to say on the subject was said several years ago in the Guy's Hospital Reports, and is not in any way inspired by that discussion. I say this because I had independently arrived at certain opinions as the result of my own observation, and they are therefore additions to any consensus that may be in course of formation on the disease. I had it on my lips to say that I have nothing new to add to what I wrote in 1887. But I have this addition to make, that whereas I thought that there was a neurotic element in the disease then, I think still more so now, with a considerable addition to my then experience. Of late years the explanation of the attacks has all gone upon one line, that the disease is due to a rise in tension in the arterial system, and this suggestion we owe chiefly to an observation of Dr. Lauder Brunton. The late Dr. Hilton Fagge adopted that explanation, and considered the fact sufficiently established by the therapeutic results so frequently obtained from the use of the drug recommended by Dr. Brunton on the ground of his observations. But these observations were made upon a case of angina with aortic regurgitation, and I do not think they carry much weight for the general run of cases. Angina pectoris clearly comes on in some cases of advanced heart disease associated with high tension, and sometimes this is so with aortic disease, sometimes with the large and dilated heart of renal disease. But it is only quite exceptional that this result happens in these diseases, for one case with angina there are many that show no such feature; and, on the other hand, I consider that the characters of the pulse in the greater number of cases enables us to say that the arterial tension is not high. There can be no doubt that angina comes about through a number of conditions, in which the only common factor is muscular fatigue. Arterial tension will produce this; so also will dilatation; so also will badly nourished muscle, whether this be due to starvation from disease of the coronary arteries, to senile degeneration of the muscle, to fatty changes, to ptomaine-poisoning, to the circulation of uric acid in the blood, and so on. And the remedies that are so useful, nitrite of amyl and nitro-glycerine, without throwing any doubt on their power of relaxing arterial tension, are none the less also relaxors of muscular spasm and cramp. I believe it is by virtue of this power more particularly that they work their effect in the disease under consideration. This hypothesis of heart cramp consequent upon heart fatigue is one that adapts itself to all the conditions under which angina is known to occur. But I am only concerned to-night with that form of the disease that occurs without any definite structural change; with those cases in which apparently healthy men are suddenly seized with pain which may kill them within a very short space of time, and yet the heart's action may be hardly, perhaps not at all, disturbed, and the sounds are practically normal. Supposing that the attack passes off, it leaves behind it the painful uncertainty, such as hangs over the epileptic, that another may come at any time. Trousseau, with his clinical acumen, seized upon this parallel with epilepsy, and considered some cases to be of the nature of an epileptiform neuralgia, and others also of a neuralgic nature from their frequency in the gouty. There are, indeed, several features of many of the attacks that further this idea: they are often accompanied by troublesome flatulence, by flushings in the head and face, by tingling in the arms, which all remind one of the erratic performance of electric apparatus during violent atmospheric disturbances. I have suggested, too, that in the crises of tabes dorsalis and diabetes there are instances of severe abdominal neuralgia, to which this thoracic crisis or angina is in many respects comparable. I may further add that it is often associated with a very sudden bronchial storm that can only be called acute bronchitis; and although we make much of it as a distinct affection, it is closely allied with, and sometimes very difficult to distinguish from, the attacks of air hunger in their more extreme degrees that are seen in uræmia and in states of cardiac failure. These and such as these are probably all ordained from a worried nervous centre.

Now these cases of angina that exhibit a distinctly neurotic type are they that loom more largely as one's experience grows, and which enshroud the whole subject in difficulty. I look up my notes of angina, and where it was obviously due to disease of heart or kidney they are gone; but where there was no discoverable affection I could give several where the disease has been absent several years; I could give others where the recurrence has been frequent and yet no harm done, the attacks being, it is needless to say, mild ones. And then there are a very large group of cases where one remains in doubt whether the symptoms have any import of serious kind. As a good illustration of this sort I may mention the case of a man who came under my notice only a few days ago. He is forty-seven years old, and this is his tale: His father died of Bright's disease. A year ago he had much worry with the illness and death of his wife, and at that time he had an attack of paralysis of his sixth nerve. His trouble is flatulence. He fills with wind after his meals, generally some two hours after, and it not only wakes him up, but he cannot walk more than a few minutes without stopping. The wind seems to get up under his heart. If he can rest comfortably in a chair he would be free; but as soon as he gets into action, as he calls it, a fermentation seems to start, and fills the top part of his body. His complaint has upset him and made him nervous, and now if anything worries him an attack comes on. Now with all this rigmarole poured into my ear you will not wonder that I thought him a wretched neurotic, and more particularly because he clinched his doleful tale by, "Mother says we are a windy family." But as I talked to him I found that he had had bad pain frequently when out walking and on going up slight hills, and that a few seconds' rest relieves the pain; and on he goes again. He further volunteers the statement that when the pain is bad he could not move a step even to grasp a thousand pounds. Add to this that he had a very metallic and ringing second sound, and that his arteries were thick; and I ended by thinking that we had, under the garb of a rather pronounced neurotic temperament, to do with a true angina. And in relation with this case I will mention another where I made a mistake by doubts of this kind.

A lady aged sixty-one, who had had a good deal of fever in India, and who for many years had neuralgia in the ovarian region, which as it passed off was replaced by neuralgia in the head, for some months had had a great deal of discomfort in the chest and throat. She had been seen by a very eminent physician in London, and nothing but incipient asthma discovered. She had been treated by bismuth, and soda, and such like. But she got worse, and used to sit gasping over the fire at night, with a nasty pain in her chest and a choking feeling in the throat, but no palpitation. She had got decidedly better of late under strychnia and nitro-

Digitized by Google

glycerine tablets, but she had rather a bad pain the night before I saw her. I judged her from her manner to be decidedly neurotic. She had a quick pulse, and complained of a tingling in her arms down to the tips of her fingers, but she moved about without distress or shortness of breath. The heart was evidently large and dilated; and there was a basic systolic aortic murmur of no great intensity. There was no sign in any of the viscera that the heart was failing. It seemed from all the evidence at my disposal that the heart muscle must have failed of late, and that the angina was due to this cause, and it seemed that, as she had improved under careful treatment, there was every hope that she might continue to do so. Moreover, it was impossible to be sure how much of the pain and choking sensation she suffered from was due to her neuralgic habit. Altogether I judged she might move about a little more and take her tablets of nitro-glycerine a little less, for I was rather afraid that she might get her nervous circulatory and muscular systems, whichever of these was acted upon by the remedy, into an unstable or oscillatory condition that might render her recourse to such means of too frequent occurrence. I know not what extent of freedom she considered my advice warranted, or even if she had acted on it in any way; but, anyhow, it clearly tended in the wrong direction, and three or four days after I saw her she was suddenly seized with a bad attack of pain on retiring to her room at bedtime, and she died.

The remedy for the anginal paroxysm is unquestionably nitro-glycerine or nitrite of amyl, and perhaps in so terrible a disease, and one in many cases of which it will ever be difficult to say whether any structural change is at the bottom of it or not, it may seem unwise to go behind the fact that we have a drug that in most cases has a decided power. But it is not really so, because no thoughtful man can have seen many of such cases without having often asked himself the question whether he is doing the best for the patient by keeping him from all exertion and telling him to consume a tablet when his pain threatens. And this much is certain, that, control it as much as the remedy may, it is in a fair proportion of cases only controlling a symptom, and the cause of it is deeper. In my opinion, then, angina sometimes constitutes a disease for which the gastric crises of locomotor ataxy and diabetes afford the nearest parallel; in others, perhaps, the condition of calf cramp comes nearest to it in likeness. In the one it may possibly be due to the uric acid diathesis, in others to the explosive nervous discharges that are well known to take place in the worried and overworked. I must not take leave of the subject of angina, though, without alluding to that always to me curious and interesting affection of women—the common and well known pain in the left side. Has it or has it not anything to do with the true disease? It would appear to be a very troublesome affection; it lasts so long and is so difficult entirely to displace. It is curious that it should occur so seldom in men, but one may suppose that this has to do with the associated anæmia with which it so commonly occurs, and which in anything like a corresponding degree is so seldom seen in males. And the fact that it does so occur in anæmic women only is perhaps an evidence in favour of it being something of the same kind as the true disease, for if, on the one hand, we consider angina as a condition due to fatigue, we have in these women the bloodless condition best suited for its easy production; if, on the other, we like the better the neuralgic origin, we have, too, under such circumstances, all the elements that seem best fitted for the calling out of the pain, and abundant evidence that it is the parent of any number of neuralgic affections. But whether this pain in the left side be related to true angina or not, it is quite certain that, except there be a probable cause for it in the existence of cardiac disease, true angina never occurs in young women; and when I consider that I have several times been asked to see young people supposed to be suffering from this serious disease, I imagine that the fact is not known so widely as it might be.

These constitute, I think, the most prominent circulatory conditions that can be fairly contended to be due to neurotic outbursts. But there are others of which, had I time, I should have liked to have given what evidence there may be in favour of a nervous fault of some kind being at the bottom of them. And of these other states I should have most to say, perhaps, in favour of the neurotic element in chlorosis. We are all familiar with the fact that severe shocks occasionally produce a sudden and bad form of anæmia; that observation is as old as the hills. But I think I could show that chlorosis is a disease that occurs in families, that it is associated with well-marked vagaries of nervous action, and that it is a disease that dogs the patient and is liable to relapse from time to time. I cannot, however, pursue the subject here, for I must in the next lecture pass on to consider the abdominal neuroses.

Clinical Lectures
ON
STRICTURE OF THE ŒSOPHAGUS,
WITH FOURTEEN ILLUSTRATIVE CASES, IN FOUR OF WHICH GASTROSTOMY WAS SUCCESSFULLY PERFORMED.

BY DAVID NEWMAN, M.D.,
SURGEON TO THE DEPARTMENT FOR DISEASES OF THE THROAT AND NOSE AT THE ROYAL INFIRMARY, AND ASSISTANT SURGEON TO THE WESTERN INFIRMARY, GLASGOW; PRESIDENT OF THE GLASGOW PATHOLOGICAL AND CLINICAL SOCIETY.

LECTURE II. (*Concluded.*)

THE diagnosis of organic stricture is usually easy. In this disease the points to be considered are similar to those laid before you in discussing the diagnosis of cancer of the gullet, so that I need not now repeat what I then said. The history of injury, followed immediately by painful deglutition, which after a few days or weeks passes off, and is, at a more remote date, followed by a steadily increasing dysphagia, unassociated with pain, hæmorrhage, or enlargement of lymphatic glands, points to organic stricture. In many cases, however, a clear history cannot be made out. The patient may have injured himself while under the influence of alcohol, during an attack of insanity, or for suicidal purposes, under which circumstances no definite history can be had, or the injury may have been received so long ago as to pass from the memory of the patient. Again, it must not be forgotten that injury may lead to carcinoma, as well as to cicatricial stricture, but as a rule it is protracted irritation—for example, the repeated swallowing of strong alcohol—that brings on malignant disease, whilst transitory and severe irritation produces a cicatricial stenosis. The absence of pain, of hæmorrhage, and of enlargement of the lymphatic glands is, as a rule, a most important indication that the stricture is traumatic rather than malignant. But while this is so you will not uncommonly meet with cases of carcinoma where, during almost the entire course of the case, not one of those symptoms is present. The history of the case, the age of the patient, the character of the dysphagia and of the discharges, usually lead you to a correct diagnosis.

Tertiary syphilitic disease may cause dysphagia either by the formation of a gumma or by the contraction of an old cicatrix. Two years ago a gentleman came from New Zealand to consult me regarding a marked difficulty he had in swallowing, and on inquiry I found that the dysphagia had developed slowly and steadily during the previous five months, and was unassociated with pain except on swallowing. There had not been any hæmorrhage, and until recently he was able to swallow semi-solid food. On examination I found a swelling behind the larynx, which pushed that structure forwards and to the left side, but did not interfere much with respiration or phonation. On passing a round No. 10 bougie a distinct obstruction was found behind the larynx, but the growth seemed to me to occupy the posterior wall of the gullet only. This circumstance made me inquire more carefully into the history of the patient, who informed me that he married immediately before leaving this country twenty-five years ago, that he had a large family, and that he always enjoyed perfect health. After much difficulty I succeeded in collecting facts which proved to me beyond doubt that four years before emigrating he suffered from a hard chancre, but after the first eighteen months he suffered from no constitutional symptoms until the growth in the œsophagus formed, and which I diagnosed to be a gumma. The patient was

Digitized by Google

placed upon mercury and iodide of potassium, and within six weeks the growth disappeared. This is the only case of syphilitic disease of the œsophagus I have seen.

Only a few words require to be said regarding spasmodic stricture of the gullet. This disease is neither so serious nor so common as the lesions we have been considering up to the present time. You have not seen a pure and simple case of spasmodic stricture of the œsophagus during the present session, but you have observed two cases in which cicatricial constriction was associated with contraction of the muscular structures. And here I may observe that I question very much the existence of spasm of the fibres of the muscular coat in an otherwise healthy œsophagus. In the examples of this disease which I have had the opportunity of observing, the lesion seemed to me to be very similar in its pathology to spasmodic stricture of the urethra; that is to say, the spasm was partly induced by undue local irritability, and partly by the temperament of the individual.

CASE 13.—In February of 1890 a very instructive and interesting case came under my notice. A man about twenty years of age consulted me, and stated that six weeks previously, while dining with a friend, a spoonful of soup which he had swallowed was suddenly and forcibly ejected from his throat; on again trying to swallow he found it impossible to take either fluid or solid food, but in the course of the evening he was able to enjoy a good meal, without any difficulty in swallowing. From that time till I saw him he complained of more or less dysphagia every day. On some occasions it was slight and could be easily overcome, while on others he experienced a complete inability to take any kind of food, or when he did succeed in forcing diet into the œsophagus, the bolus was immediately expelled with considerable force. He found that when he took food in company with others that he was more likely to suffer from dysphagia than when he took his meals alone. These attacks as a rule came on towards the end of a meal. When I saw him for the first time he was much excited, so that it was with the greatest difficulty I made a satisfactory examination. On passing a large and firm bougie I found it could be easily introduced into the œsophagus; but when it reached a point ten inches and a half from the teeth it met with a very marked obstruction, which, however, was overcome by steady and continued pressure. At a subsequent visit I introduced a small-sized gum elastic instrument. It detected an obstruction at the same point, but immediately the bougie was ejected and thrown into a coil in the pharynx. I then passed a larger and firmer bougie, and as soon as it reached the obstruction I released my hold, when the œsophagus forcibly and quickly contracted so as to throw the instrument out of the patient's mouth. The man was then placed under chloroform, and an examination was made with the electric œsophagoscope, when I found at a point corresponding to the site of obstruction an inflamed area about an inch in length, but free from ulceration. I kept the patient in bed, and directed that he should have only barley water, milk, and soup by the mouth, supplemented by nutrient enemata. Within three weeks he could swallow without any attack of dysphagia; on the twenty-ninth day after the treatment was commenced I could pass a full-sized bougie without finding any obstruction, and since then the patient has enjoyed perfect health.

Spasmodic stricture is not frequently observed in men; as a rule it occurs more commonly in the female. This disease is frequently met with in young women between the ages of twenty and thirty; but it may be seen in persons under these ages or even later in life. It is not infrequently associated with nervous affections, such as epilepsy, chorea, hysteria, or dyspepsia, intestinal worms, tetanus, hydrophobia, and hypochondriasis, or it may be induced by uterine and ovarian disease, or associated with gout and rheumatism. You will therefore observe that it is not only necessary to consider the symptoms of local disease, but it is also imperative to inquire into the general health of the individual, and determine whether the patient is the subject of any other lesion likely to induce, either directly or indirectly, spasm of the gullet.

The statements of patients suffering from this disease must be received with caution, as they almost always greatly exaggerate their suffering; and although they inform you that they have been unable to swallow any food for days or weeks they almost invariably are well nourished, presenting, therefore, a very different appearance from those who are affected with organic or malignant stricture. While by themselves, such patients usually succeed in taking a good meal, but if watched, or even in the presence of others, they fail to swallow food. From what I have already said you can have little difficulty in distinguishing this disease from those previously brought under your notice. The symptoms occur in excitable subjects, the dysphagia comes on in paroxysms usually in the middle or towards the end of a meal. Food is regurgitated with force immediately after swallowing, the point of obstruction varies from time to time, and when a bougie is passed and steady pressure exerted the stricture is overcome, or the instrument, if relieved, is forcibly ejected; there is no emaciation or cachexia; pain is not complained of as a rule, unless when a bougie is being passed, nor is there any enlargement of lymphatic glands.

Having laid before you the various diseases and the methods of distinguishing the one from the other, I may now ask you to consider the general question of prognosis in cases of stricture of the œsophagus. The prognosis in cases of carcinoma depends upon the nature and situation of the disease. If no operation be performed for the relief of the patient, then the great probability is that he will die from starvation sooner or later, according to the situation of the primary disease. When the tumour originates in the upper part of the gullet, complete dysphagia may develop within a few weeks of the onset of the first symptoms, and the patient may succumb after only perhaps two months' illness. On the other hand, carcinomatous disease of the lower end of the gullet may run a very slow course, so that the patient may live for many months. Again, cases of scirrhus are as a rule more chronic than those of epithelioma or soft cancer; and, indeed, as I have demonstrated in the cases shown to you, the progress of the first-mentioned variety of cancer is far from rapid. In some instances—as, for example, in Case 7—considerable improvement may take place as a result of rest to the parts after gastrostomy, the rest permitting inflammation and spasm to subside, or, as in Case 5, the power of swallowing may improve as a consequence of ulceration and sloughing of the tumour. When the latter condition is developed new dangers present themselves—namely, rupture of the œsophagus into the surrounding parts. Cases have been recorded where communications have been established between the gullet and the posterior mediastinum or the peri-œsophageal adipose tissue in the neck, where inflammation of a more or less serious character has resulted therefrom. But in the great majority of instances, on account of the chronic local irritation, adhesions form, which unite the gullet to the neighbouring organs. For example, in the cavity of the thorax the œsophagus may become bound to the pericardium, pleura, air passages, or to the great bloodvessels, into any of which structures rupture may take place. I have already shown you an instance (Case 5) where rupture occurred into the aorta, and resulted in fatal hæmorrhage, and on the table I have four specimens, three of which I placed in the museum. These illustrate how death may be caused by a communication being established between the œsophagus and the air passages. In the first specimen the epithelioma occupies the œsophagus at the level of the bifurcation of the trachea, and led to acute inflammatory changes in the lungs, the apices of which were softened and completely destroyed, while the pleuræ were adherent. The second case is very similar. The tumour occupies the same position. The œsophagus is completely destroyed by gangrene for a distance of about two inches, and the left lung was, at the post-mortem examination, found to be also gangrenous. The third case is one of special interest, as the first stage of gastrostomy was performed by me previous to the occurrence of rupture.

CASE 14.—The patient, H. P——, aged sixty-six, a warper, was admitted to the Glasgow Royal Infirmary on May 18th, 1888. He stated that about six months previous to admission he became affected by a cough, which was spasmodic and very irritating, but unassociated with much expectoration. Up till the time of admission this cough has been present without cessation, and during the last three months the patient has had considerable difficulty in swallowing. This dysphagia has daily increased. At first he experienced difficulty in swallowing solids, and afterwards in swallowing semi-fluid food, but now even simple fluids, such as milk or soup, pass into the stomach with difficulty. The patient has always enjoyed good health, has not suffered from specific disease, nor does

Digitized by Google

he know of having sustained any injury to the gullet. On passing a bougie into the œsophagus an almost complete obstruction was discovered fourteen inches from the teeth. On account of the situation of the stricture—namely, the bifurcation of the trachea—it was considered advisable to make a critical examination of the chest, in order to discover whether or not the obstruction might possibly be due to the pressure of an aneurysm. I asked my colleague, Dr. Gemmell, to make a physical examination, and he assured me there was no positive evidence of aneurysm. I then endeavoured to pass a small-sized bougie, and after some difficulty succeeded in pushing a No. 8 through the stricture. On June 13th the difficulty in swallowing had so increased that it was evident that unless a radical operation was performed the patient would speedily succumb. After a consultation with my colleagues, it was agreed that gastrostomy should be performed immediately. I therefore operated in the same manner as in the foregoing cases, and nourished the patient by nutrient enemata and suppositories. After the operation the patient was able to swallow small quantities of milk without much difficulty. During the first twenty-four hours he seemed to gain strength, but on the second evening it was noticed that when he swallowed milk or other fluids they immediately caused an attack of coughing, during which the food was expectorated. This change suggested rupture into the trachea, and prevented the administration of food by the mouth. On the third day after the operation symptoms of acute bronchitis developed, and the patient was so weak that little hope was entertained of his recovery, and on the fourth day he died from collapse, associated with considerable difficulty in breathing. At the post-mortem examination an epithelioma of the œsophagus was found at the level of the bifurcation of the trachea. The surface of the growth was slightly irregular, and its lower and upper margins overlapped the healthy mucous membrane. The œsophagus was firmly adherent to the aorta, to the trachea, and to the bronchial tubes, and there was a rupture large enough to admit the little finger between the gullet and the left bronchus. This perforation was evidently of very recent origin, its edges being soft, irregular, and sloughing. No secondary formations were discovered.

The fourth case was placed in the museum by my predecessor, the late Dr. David Foulis. It is one of epithelioma of the œsophagus ulcerating into the right pleura. The preparation shows the lower part of the œsophagus, the cardiac orifice of the stomach, and a portion of the liver. The lower part of the œsophagus is occupied by a tumour which involves the entire circumference of the tube, and presents an extremely irregular and somewhat warty surface. The tumour occupies about three inches and a half of the length of the œsophagus, its lower margin being about two inches above the cardiac orifice. But just beneath the lower termination of this main tumour there is an isolated globular mass (seen in section) which projects into the tube, and is attached by a comparatively narrow base. Towards the right side the surface of the general tumour presents ulceration, and here a direct communication exists with the right pleura. In the specimen a portion of the pleura is preserved, and the aperture is shown, the pleura being held on the stretch by a piece of whalebone. On examining this pleura before any of the contents of the chest had been disturbed, it was found to contain a grumous fluid with the sour odour of the contents of the stomach, while the surface of the membrane was coated with soft lymph. The tumour in the œsophagus presented the structure of epithelioma, and the same form of disease was found in numerous lymphatic glands. The liver also and the kidney contained a few secondary formations. The history of the case, which was under Dr. Perry, shows that symptoms of difficulty of swallowing, and pain began about five months before death. A violent pain attacked the right side of the chest two days before death, and auscultation detected the usual signs of pleurisy.

These cases illustrate sufficiently the mode of death otherwise than by starvation. I have, however, collected the statistics of 566 cases of carcinoma of the œsophagus, with the following result respecting the cause of death:—

Collapse and exhaustion	390
Inflammation of lung, including gangrene ...	91
Pleurisy	53
Peritonitis	17
Perforation into heart or bloodvessels	15
	566

The prognosis in benign tumours of the gullet depends upon the position, size, and rapidity of growth of the neoplasm, and whether or not it can be removed by operation. When situated high up it may be cut off or ligatured, or if pedunculated and soft, the parasol-probang may dislodge it. But should the tumour be situated so as not to be capable of removal, then, in expressing his views as to the prospects of the patient, the surgeon must consider the situation of the growth and whether or not it is likely to interfere with other functions than those of swallowing. When the growth is slow, usually compensatory dilatation of the œsophagus occurs. The prognosis in cicatricial stricture of the œsophagus depends upon the extent of the stenosis and the period at which the patient is seen. Unfortunately, the tendency is for patients to delay seeking advice till the gullet is almost completely closed, and then not infrequently the obstruction is so great that it is almost impossible to dilate with bougies. The most difficult cases to deal with are those of attempted suicides who have swallowed strong mineral acids. In such instances the patients delay asking advice till the very last, and usually the injury is very extensive and the stenosis intractable. When the poison is taken by accident the quantity swallowed usually is much smaller, and the stenosis more limited. Before forming an opinion as to the ultimate result you must also inquire whether there is more than one stricture, and ascertain their situation. When a bougie, even a small one, can be passed the prospect of ultimately dilating the stricture is considerable, but if no instrument can be got through, the danger to life is very considerable. When it is ascertained that the organic stricture is incurable, then resource must be had to gastrostomy. It is in these cases that this operation is most successful if performed sufficiently early. Cicatricial stricture may exist for many years before the patient succumbs to inanition. The narrowing of the gullet may take place slowly, and in order to overcome the greater difficulty in swallowing a gradual hypertrophy of the muscular fibres occurs above the constricted point. Therefore the muscular force being increased, the patient may succeed in taking nutriment through a very small passage. The whole question of treatment now comes to be considered, but this I leave to our next meeting, which we shall devote entirely to the subject.

THE BEARING OF RECENT BIOLOGICAL RESEARCHES ON THE PRACTICE OF MEDICINE AND SURGERY.

BY G. SIMS WOODHEAD, M.D., F.R.C.P.EDIN.,
DIRECTOR OF THE LABORATORIES OF THE ROYAL COLLEGES OF PHYSICIANS (LOND.) AND SURGEONS (ENG.).

(*Continued from page 188.*)

IN several recent papers, especially those from the pens of Metchnikoff, Ballance, Sherrington, Ziegler, Burdon Sanderson, and Ruffer, many interesting facts bearing on the healing of wounds have been recorded. These facts have been interpreted by different observers according as they were biased in favour of the greater importance of chemotaxis or phagocytosis in the setting up of inflammatory processes. Whatever may be the explanation given of these facts, they are placed on record for each to draw his own conclusions, and, without going into detail, we may give in a summarised form some of the more important of these observations, especially as they bear on the process of healing.

It is well to bear in mind that the process of repair, whether in the healing of ulcers, the making good of ruptured muscle, or the union of the fractured ends of bone, is essentially the same; the appearances and results, however, being considerably modified according to the amount of tissue lost, and also according to the amount of extraneous or temporary supporting material that is thrown out into or left in the wound—material which may serve as a scaffold for the support of the true organising tissue by which it is ultimately absorbed. Further, according to the amount of stimulation or external irritation the healing process may be considerably modified, so that we may meet with all intermediate stages from heal-

Digitized by Google

ing by first intention to healing of an ulcerated surface by granulation. We know, for example, that if a clean incision with a sharp knife be made into soft tissues, the hæmorrhage be allowed to cease, and all blood be carefully sponged away before the two surfaces are again brought into apposition and then kept there by gentle pressure, in the course of a few hours the wound is so far healed that it requires some little effort to again open it up, and in three or four days healing may be almost complete. In such a case the amount of lymph thrown out is exceedingly small, just enough to form a glazing over the cut surface; there is little distension of the blood vessels, and the surfaces are only slightly redder than normal; so that if the film of coagulated fibrine is merely sufficient to keep the lips of the wound in temporary apposition, the process of organising can go on under the very best possible conditions. The less lymph there is to be removed by the leucocytes—the fewer vascular changes we find at the seat of operation, the less bridging across the connective-tissue cells and the embryonic bloodvessels have to do—the shorter is the time required for the process of organisation and healing. Any method that the surgeon can devise to bring about the conditions above mentioned will favour more rapid and at the same time more perfect results. If Metchnikoff's phagocytes have taught us nothing else, they have brought into prominence the all-important fact that before repair of any kind can go on in the body all injured and dead tissues must be removed. If they are not removed by the surgeon, or are actually brought into existence by the surgeon's knife or by his rough handling or injudicious use of chemical substances, they will be removed by a force of scavenging phagocytes that will be brought up for the purpose, and until these have done their work the process of repair cannot be completed; for suppuration, whether in a wound on a small scale or in an abscess on a large scale, is the result of an attempt on the part of the organism to free itself of materials that are interfering with the process of repair. We now know that this suppuration was by the older surgeons looked upon as a good, healthy process, because by its presence it affords evidence that the tissues of the patient, as represented by the leucocytes, are still able to react, and are setting up a barrier against the invasion of foreign matter at the same time that they are endeavouring to get rid of it. Theoretically, of course, there can be no healing without inflammation, because no incision can be made into the tissues without some parts being injured and bruised, even when the incision is made with the sharpest of knives; but this inflammation, with its vascular and connective-tissue changes, may be kept within such limits that we say inflammation is practically absent, its manifestations are so slight. These considerations have led surgeons to exercise infinitely greater care than they did at any previous time in the treatment of any parts on which they have to operate. A blunt knife is rejected not merely because it interferes with the neatness of the operation, but because the bruising of the tissues caused by the blunt edge, as compared with a keen blade, may make all the difference between healing by first intention and a prolonged and tedious process. Any rough handling of delicate tissues, any squeezing with forceps, any bruising of muscle or of connective tissue when prising out fragments of bone, are now carefully avoided because the surgeon is satisfied that the more these tissues are injured so much the less able are they to perform their regular work, so much the more do they become effete, and so much the more do they require to be removed by an exaggeration of a normal process—an exaggeration which merges into or constitutes a process of inflammation.

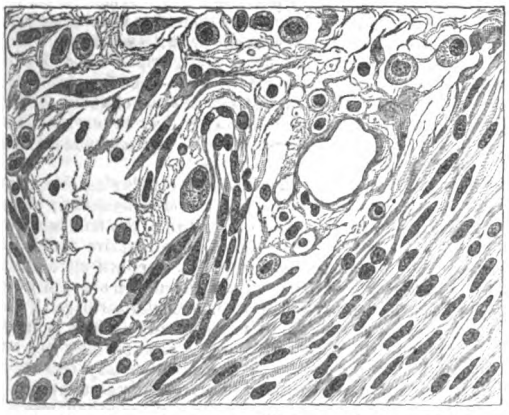
It was at one time held, first by Cohnheim and later by Ziegler, that leucocytes are the all-important factors in the process of repair, that not only do they remove dead material, but that from them are formed the new tissues by means of which any gap is filled up. This doctrine, at one time so popular, and still accepted by many, was very keenly combated by several observers abroad and by D. J. Hamilton in this country more than a dozen years ago, who held that the leucocytes simply play the part of scavengers and feeders, and that the actual process of organisation is carried on by larger cells, which result from the proliferation of connective tissues and other cells. Returning to our collection of pus cells—which are really leucocytes that have succumbed during the active scavenging process,—if it be not of large size it must be ultimately absorbed, and in this process of absorption we find that another factor comes into play. Leucocytes at the margin—that is, those that have come directly from the dilated vessels—do part of the work, but the main bulk is carried on by the larger connective-tissue cells, which after some time (that is, much more slowly than leucocytes can be brought up) proliferate where foreign bodies or irritant materials of any kind are present. The wall of an abscess in such a stage may be looked upon as a granulating surface, similar in many respects to that of an ulcer throwing off dead cells, the vascular loops, with the appearance of which all are familiar, the exudation of leucocytes, the proliferation of connective-tissue cells are much the same on any healing surface; but it is specially on the presence of the proliferating connective-tissue cells that healing depends after the pus has been evacuated or absorbed. The leucocytes may play a very important temporary part, as we have

FIG. 1.

Engraving of a healing wound of stump about fifty hours after operation (× 75). Near the surface (*a*) is a mass of detached epithelium mixed with blood and fibrinous lymph. Beneath this (*b*) to the left of the lips of the wound the epithelium is seen. The dark band (*c*, *e*) marks the line of incision, and is due to the presence of an enormous mass of blood pigment, much of which has been taken up by microphages or small leucocytes; whilst at certain points some larger cells, macrophages (not seen in this illustration), contain masses of pigment and small cells in various stages of degeneration in which in turn pigment may still be seen. The larger black patches (*d*) represent masses of blood pigment, with here and there some shrivelled or degenerating red blood-corpuscles. The small black points represent leucocytes, which are present in increased numbers only where the pigment is to be removed in order that the healing process may be completed.[1]

already seen; but the connective-tissue cells, whilst continuing the scavenging and helping to remove the leucocytes that have already played their part, ingesting them, and utilising them as food, have a further work to do. They form not only the new connective tissue, but also the embryonic bloodvessels, the new bloodvessels being apparently nothing more than tubes formed of large connective-tissue cells of the endothelial type.[2]

Growing from the cells which actually form the walls of the minute vessels, or from cells immediately surrounding



[1] The drawings of the engravings illustrating this paper have been made for me by Mr. Richard Muir, to whom I am greatly indebted for the extreme accuracy with which he has transferred to paper the appearances presented under the microscope.

[2] The mere mechanical protrusion of vessels on unsupported surfaces may be an important factor in vascularisation, but there are certainly other and even more important processes which can usually be followed out near the surface of a healing wound.

Digitized by Google

them, there may frequently be observed single rows or small columns of cells which appear to shoot outwards into the fibrinous lymph; into these columns the blood usually makes its way, as a channel or lumen is formed between which and the original vessel communication is maintained or set up. In some cases these new vessels appear to grow outwards and the proliferation to take place always a little in front of the advance of blood, but in others it appears as though a single row of cells is formed, and these, proliferating, form a more complete column, which gradually opens up to receive blood. It is scarcely necessary to follow out the healing process further, as it is with the points here mentioned that we have specially to deal; but we may point out how intimately inflammatory and healing processes are bound up one with another, and how every step in the process is merely preparatory to a succeeding one, and that in many, or even in most, cases temporary makeshifts are resorted to in order that the way may be prepared for the formation of more permanent structures. First, there is the dilatation of the bloodvessels, accompanied by softening of the cement substance between the endothelial cells and emigration of leucocytes (probably through

FIG. 2.

Engraving of a growing new vessel in a granulating wound (× 450). In the middle of the illustration is seen a channel composed of flattened cells derived apparently from connective-tissue cells. Above and to the left the spindle-shaped cells and the large macrophages (or plasma cells, as they are sometimes called), each with a single nucleus, are well seen. A few leucocytes may also be seen. The method of formation of the bloodvessel from the advancing row of connective-tissue cells is well seen.

this softened cement substance) and effusion of serum, all this resulting from some injury or irritation to which the tissues are subjected, the various processes at this stage appearing to be associated with the checking or counteraction of the presence of irritant or foreign bodies. When these exudations have done their work and have localised the area of action of the irritant or injury, and have formed a sharp line of demarcation between the healthy and the abnormal tissues, they have no longer any function to perform; they in turn become foreign bodies, and as such must be removed. Acting as foreign bodies and along with the other irritants present, they induce proliferation of the fixed connective-tissue cells, a proliferative process which is not confined to the endothelial cells of the lymphatics, but is also participated in by the endothelial cells that form the walls of capillary vessels. It might at first sight appear that the accuracy of the observations as regards the proliferations of the endothelial cells of the capillaries can scarcely be relied upon, and that little corroborative evidence has yet been brought forward in support of such accuracy; but we have not far to seek for collateral evidence of a very important nature, though such evidence is not often quoted in this connexion.

It is a matter of common observation that in certain conditions of the lung and kidney where we have irritant material circulating in the lymphatics and setting up proliferative changes in the connective tissue, the more marked these changes are in the adventitia of the vessel—that is, in its connective tissue sheath,—the more likely are we to find proliferation of the cells of the intima, with in some cases a shooting of vessels into the new cellular mass. The processes in the outer and in the inner coat go on simultaneously, and we have endarteritis obliterans associated with connective-tissue proliferation around the vessels. Of course it will be objected that the irritant material acts on the intima and on the connective tissue from different points, and that when tissues are stimulated in this slow chronic fashion, they proliferate and give rise to the changes we have described. It must be pointed out, however, that the results are identically the same; in both we have a cellular connective tissue, and in both young bloodvessels are formed just as at the surface of a granulating wound, and the endothelial cells in the bloodvessels, whether large or small, react as do connective-tissue cells, whether these be in the adventitia of a vessel of considerable size or in the new granulation tissue surrounding the capillary vessels. In no case can any transition from a leucocyte to a connective-tissue cell be observed; the leucocytes are phagocytes and little else, though, as we shall find, they probably play a most important part in nutrition, a part which only in recent years has been assigned to them. The connective-tissue cells, on the other hand, have an all-important part to play in the building up of new tissues in addition to their functions of metabolism. It may be, of course, that this distinction into leucocytes and fixed connective-tissue cells is, after all, somewhat artificial, as the differences in character may he only temporary, and may be due merely to the different conditions under which they are compelled to exist and proliferate; but whether the distinction be artificial or not, there remains the fact that we have these marked differences, and that in any case it would require a considerable time for these various cells to become transformed one into the other. There can be no doubt, of course, that the connective-tissue cells under the stimulus of certain irritants proliferate rapidly, their usual appearance is somewhat departed from, and we have what Virchow would call a "metaplasia." Then, again, all that we know of the source of a true leucocyte would lead us to suppose that these in turn are derived by a process of proliferation from endothelial cells, very similar in structure to the large endothelial cells that we speak of as fixed connective-tissue cells, but the fact still remains that we have these important differences.

This brings me to an exceedingly interesting and suggestive line of thought that has been opened up by Ruffer[3] in his paper on the Phagocytic Action of the Lymphoid Cells of the Intestine, by Gulland[4] in his paper on the Development and Structure of the Tonsils, and by Stiles on the Structure of the Axillary Glands.[5] We have already seen that under ordinary conditions there is an accumulation of leucocytes and a proliferation of connective-tissue cells at any point where effete matter has to be removed or foreign matter got rid of. We also know that the development of an organ or part is always followed by the development of lymphatic glands along the line of lymphatics leading from it, a development that appears to be due to the necessity that there is for the destruction of an increased amount of effete matter. Even in these glands it will be found that the two kinds of cells—that is, those large branching cells lying on the reticulum and the smaller lymphoid cells found in such numbers in the free spaces—are essentially different, and may be compared to the two kinds of cells met with in the healing wound. Here each kind of cell has its own function; but so far as we can see under ordinary circumstances the lymphoid vessels are primarily concerned in the taking up and dispersion of the substances brought to the gland by the lymphatic channels. It would appear that they do the rough work of "secondary" digestion, and that through their assistance the larger cells are enabled to go about their work leisurely and to do it efficiently. This would bring the development of the lymphatic gland into much the same category of process as those met with in a healing wound, the only difference being that in the one case we have an irritant that is applied over a considerable area and indiscriminately to all the tissues in that area; whilst in the other we have the irritant brought up by a distinct channel, by the walls of which its action is confined strictly to definite areas and tissues—i.e., those to which it is distributed

from this channel. If now we look upon this channel as breaking up into a capillary network—the capillaries of which are the spaces between connective-tissue or fat cells,—and suppose that it acts as an irritant, as in a healing wound, the development of a lymphatic gland, with its lymph follicles, its delicate reticulum, its slowly proliferating endothelial cells and its accumulation of lymphoid cells is comparatively easily explained. The enlargement of this gland under increased irritation, the enormous proliferation of both kinds of cells in such conditions as typhoid or septic irritation, and the like, and the actual suppuration that occurs when these processes are very intense are readily understood. The more we think over the matter the more are we struck by the similarity of the processes above-mentioned, and the more does it appear necessary that the development of the lymphatic gland should be studied in order that its importance in the economy in the localisation of disease may be appreciated. The time has now gone by for connective tissues to be looked upon merely as padding and support, or even as tissue in which fat may be accumulated and leucocytes formed. These connective-tissue cells along with the leucocytes play a far more important *rôle*. Various metabolic products have been found in them, and the liver is gradually being ousted from its high place as the great metaboliser of the body, and its place is being taken, in part at any rate, by the connective-tissue cells and leucocytes; whilst it is further acknowledged that even where the liver is allowed to retain any metabolic function it is often merely to complete work that has already been commenced by the tissues of which we have spoken, and that so far its functions are excretory rather than secretory. In making such statements as these one must be extremely guarded lest functions of which hitherto we have had too exalted an opinion should now have too little importance attached to them. At present, however, there is little enough danger of the mesoblastic tissues being promoted to too prominent a position, especially if it is to be at the expense of the liver. Certainly the connective-tissue cells and leucocytes have much more in common with those of the liver than is often admitted; whilst the greater the degeneration of liver cells in any disease, the nearer in most cases does it approximate in its functions the active connective-tissue cells. In both kinds of cell we find that fat may be stored up, such fat apparently in most cases being derived from the splitting up of proteids or other substances containing the fat molecule that are brought from without. We have the protoplasm of the liver cell remaining almost intact, just as does the protoplasm of the connective-tissue cell. It, along with the nucleus, which retains the greater part of its activity, is simply pushed aside, and on the absorption of the fat resumes all its previous activity. The liver cells, too, have the power of taking up pigment derived from the blood, and in normal conditions of breaking it up rapidly, and probably of excreting the products into the bile-ducts in the form of bile-pigment. Where, however, as in chronic venous congestion, their nutrition is interfered with we find not only breaking down of the liver cells due to the internal metabolism or the conversion of their own protoplasm into fat by the breaking down of its own proteid substance; in such cases we also find that pigment accumulates in these cells, pigment that is not readily got rid of, and which remains in them just as pigment remains in degenerating connective-tissue cells or leucocytes.

(To be concluded.)

CHRONIC TRAUMATIC ARTHRITIS.

By W. ARBUTHNOT LANE, M.S.,

ASSISTANT SURGEON TO GUY'S HOSPITAL, AND TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

My object in writing this paper is to make another attempt to separate from the several groups of conditions comprised by the terms "rheumatoid arthritis," "rheumatic gout," "osteo-arthritis," "arthritis deformans," &c. one which is very definite in its history, clinical symptoms, and pathology. As far as I know, no author has recognised this class as a separate one, while pathologists do not pretend to make any such distinction. As its causation is entirely mechanical, I would suggest for it the term "traumatic arthritis," to which I would add "chronic," for the reason that the condition develops slowly, and when once produced it continues to progress during the lifetime of the patient. Some objection may be urged against the universal appropriateness of this term, since the condition to which I wish again to call attention does not always arise from the severe contusion of the joint as the result of a *single* injury; but it may, and frequently does, come about in consequence of the excessive use of a joint, or of any alteration in its normal anatomy and physiology, by means of which pressure is transmitted habitually from one bone to another in an abnormal manner; or it may result from a joint being called upon to sustain and transmit an amount of force greater than the particular human organism was evolved to support. In a paper in the Transactions of the Pathological Society, 1886, entitled the "Causation and Pathology of Rheumatoid Arthritis and of Senile Changes," I showed that the very large proportion of the pathological changes which are regarded as evidence of the so-called disease "rheumatoid arthritis" depend for their production upon factors which are simply mechanical. The careful clinical study of the conditions comprised under the term "rheumatoid arthritis" &c. by recent observers[1] has resulted in the differentiation of two distinct groups of joint diseases—one, namely, rheumatoid arthritis, in whose causation rheumatism forms no part, and whose symptoms are very complicated and by no means limited to the changes in the joints, and the other rheumatic arthritis which results solely from rheumatism. To these two groups I would then add a third—chronic traumatic arthritis,—and I would urge that while it forms a not inconsiderable share of what is clinically regarded as rheumatoid arthritis &c., it provides almost solely all the conditions which in our museums are represented as specimens of that disease.

I find that in the dead body the following changes are almost universally supposed to be characteristic of that vague condition rheumatoid arthritis, the term being here used in its older and more comprehensive acceptation, namely:—1. Removal of articular or inter-articular cartilage. 2 More or less destruction and eburnation of opposing surfaces of bone deprived of their articular cartilage. 3. The formation of cartilage, or more usually of bone, upon the margins of the articular surfaces altering their form and increasing their area. These growths may occasionally extend into the ligaments or less frequently develop primarily in them. To these changes the terms "osteo-phytic growth," "lipping," &c., are applied. 4. Hypertrophy of the synovial membrane so as to form more or less abundant masses or fringes consisting of branched pedunculated processes, which in some cases contain much fat, and in others small masses of cartilage or bone. These occupy the varying intervals between the altered articular surfaces, and often secrete an abnormally large quantity of synovial fluid. This may be so abundant as to distend the capsule and to cause much relaxation of ligaments. It is highly probable that these or similar changes may be found in patients who have been affected for many years by either of the groups of rheumatoid or rheumatic arthritis. They must come but rarely under the observation of the pathologist, and they are represented hardly if at all on the shelves of our museums.

I will now proceed to illustrate briefly the several conditions to which I would apply the term "chronic traumatic arthritis."

A man, past middle age, falls heavily upon his side, striking the great trochanter with much force. In consequence of this injury he experiences much local pain in the hip-joint, which is aggravated by movement of it. If the legs be measured they are found to be of equal length. The patient finds that after the injury his leg is not so reliable as it was before, that the movement of complete flexion of the hip-joint is accompanied with discomfort at first, and later with pain, so much so that any movement of the joint is avoided as much as possible. He also suffers discomfort or pain in the joint in damp weather, or during the cold east winds. I believe that it is the similarity of this pain to that felt by rheumatic patients that has led clinical observers to include this traumatic condition among those classified under the old headings of "rheumatoid arthritis" &c. I need hardly point out that after any injury to a bone, such as fracture &c., the sufferer often complains of the same kind of pain under the same atmospheric conditions. After a time the patient notices that the damaged

[1] Osteo-arthritis: Kent Spender. Rheumatic Diseases (so-called): Hugh Lane and Griffiths

Digitized by Google

leg has become shorter than its fellow, and actual measurement shows that this is the case. This shortening increases during the life-time of the patient if he continues to throw his weight upon the articulation. The joint becomes progressively less secure, until at length the weight of the body cannot be supported by it at all in many cases. Soon after the receipt of the injury grating can be felt on flexing or extending the joint, and this sensation becomes more marked as time goes on. If such a joint be examined after death, the head of the femur and the acetabulum are found to be completely altered in form and character. The opposing surfaces of the innominate bone and femur are rubbed down, sclerosed, and eburnated, while around these eburnated surfaces there is an abundant deposit of more or less dense bone, whose obvious function is to compensate for the altering direction in which force is transmitted through the joint and to render it as secure as possible under the circumstances. The capsule has become thin and lax, and has ceased to perform most of its normal functions. The synovial membrane is bulky in the joint and contains an abnormal amount of synovia. The causation of the several changes here described is quite obvious. The opposing surfaces of articular cartilage have been bruised sufficiently to interfere with their vitality, and there being no means of replacing the damaged tissue it is removed. The habitual transmission of force through the damaged joint results in the progressive destruction of the remainder of the articular cartilage, in the exposure, eburnation, and the progressive gradual destruction of the subjacent articular lamella of bone. These changes are followed by the others already described, the factors determining their evolution being solely mechanical. Is there any argument in favour of applying to this condition such a term as "rheumatoid arthritis" or any of its synonyms? A change, similar in character, though slighter than that just described, which develops to a varying degree in the hip-joint of labourers who are employed in carrying heavy loads, was misconstrued by anatomists, and led them to suppose that in old age the neck of the femur yielded, and that the head occupied a lower level than in the adult in consequence. In the paper already referred to I pointed out how this fallacy arose, and I have since been pleased to see that so keen an anatomist as Professor Humphry has in a recent paper denied that any such change takes place in the obliquity of the neck of the femur in old age.

The following serves as another instance of chronic traumatic arthritis. A man falls heavily on the outer surface of his shoulder. He suffers from much pain at the time, and he can neither bear the shoulder-joint to be moved nor can he perform any active movement himself, on account of the pain associated with it. If the shoulder be examined no fracture can be made out, and the outlines of the humerus and of the glenoid cavity are normal. The symptoms progress as in the case of the hip. The shoulder becoming flattened, the patient is unable to abduct the humerus, and the movements of the shoulder joint become limited finally to a moderate amount of flexion and extension. On examining the joint after death the opposing surfaces of the head of the humerus and of the glenoid cavity are deprived of cartilage, the articular layer of bone is rubbed down and eburnated, the surface of the humerus is rendered flat, or but slightly convex, being much increased in breadth by the deposit of bone upon its margin. The articular surface of the scapula has undergone similar changes. The synovial membrane is bulky and the muscles of the shoulder, especially the abductor muscles, are much wasted. Here, again, the causation is quite obvious. Force is applied to the outer surface of the humerus in such a direction that its articular surface is driven forcibly against that of the scapula, and in a direction at right angles to the surface of the latter. Changes ensue in the manner already described in the hip.

I would instance still one more example in the same joint. A man receives a heavy blow or pitches heavily on the point of the shoulder, breaking his acromion process, whose loose fragment is driven forcibly downwards upon the upper surface of the humerus, bruising its articular surface severely, together with the intervening capsule and tendon of the supra-spinatus. Degenerative changes ensue in the contused portion of the articular cartilage, and gradually extend to more or less of the remainder of the cartilage of the head of the humerus and to that of the glenoid cavity. The upper portion of the capsule, with more or less of the tendon of the supra-spinatus, is gradually destroyed, and the humerus comes sooner or later into direct contact with the movable fragment of the acromion. The constant movement of these bones upon one another results in further changes in both, the acromial portion becoming excavated, eburnated, and lipped. The intra-capsular portion of the biceps tendons is destroyed, the long head acquiring an attachment to the altered great tuberosity. Other changes develop at the same time in the synovial membrane. I would call particular attention to this last injury, as it bears in an important manner on the elucidation of the causation and pathology of chronic traumatic arthritis. I showed[2] some time ago that fracture of the acromion is of very common occurrence, and that the supposed rarity of the fracture depended upon a want of skill in recognising its existence. Since that paper I have been able to verify this statement most fully, both in the accident department, where the recent fractures were observed, and in the out-patient department, where the condition of non-union which almost always results was seen. This non-union is due to the fact that unless the accident is diagnosed, which it very rarely is, or unless it be accompanied by some more severe injury, as fracture of the upper end of the humerus, the shoulder is not kept at rest for a sufficient time to allow of the fracture of the acromion uniting by bone, and as a consequence a false joint forms. When the blow which produced the fracture was sufficiently severe to contuse the articular cartilage of the head of the humerus and the intervening soft parts, the changes I have just described follow.

Anatomists are largely responsible for the non-recognition of these fractures, since they have chosen to regard the resulting ununited conditions as examples of non-union of an epiphysis, and, so far as I can see, upon no reliable evidence whatever. Some surgeons have readily accepted the statements of the anatomists apparently without investigating them. They have, however, observed the frequent association of this so-called ununited epiphysis with the presence of so-called rheumatoid changes in the shoulder-joint, and have explained the cause of the association in various ways. One has gone so far as to assert that in cases of chronic rheumatoid arthritis of the shoulder-joint a disunion of the acromial epiphysis from the rest of the bone takes place. Such a statement hardly calls for criticism, and I only mention it to indicate the frequency with which those changes which the pathologist regards as characteristic of the disease, rheumatoid arthritis of the shoulder-joint, are found associated with ununited fracture of the acromion. Can anything be more obvious and simple than the mode of development of an ununited fracture of this process of bone, if one considers for one moment its position and muscular attachments, together with the difficulty of retaining the broken fragment at rest for any length of time, even if the fracture be recognised? The only two examples of bony union which I have observed followed a fracture of the acromion, which was accompanied by a severe comminuted fracture of the upper end of the humerus. Owing to the pain resulting from the presence of the latter fracture the shoulder was kept at rest sufficiently to allow of bony union. Though I might multiply such instances indefinitely, I think I have said enough to show that a severe injury to a joint is liable to be followed by the development of such pathological conditions as we are accustomed to regard as evidence of the presence of rheumatoid arthritis.

I will now allude but very briefly to the remarkable changes which develop in the joints of men or beasts of burden accustomed to follow some laborious occupation for many years, since I have described them very fully in preceding papers. They were all regarded as examples of rheumatoid arthritis on the post-mortem table, and also not uncommonly during lifetime. They consist in the removal of articular cartilage, the sclerosing, eburnation of the exposed bones, the alteration in the forms of the articular surfaces—sometimes by considerable excavation of bone, sometimes by the abundant deposit of bone upon the margins of the articular surfaces,—by the formation of masses of bone upon the floor of cavities—such as the olecranon and coronoid depressions,—the removal of fibro-cartilage from the sacro-iliac and vertebral joints, the formation of large prominences of bone locking these joints, the fusion of opposing surfaces of bone, &c. Again, precisely similar changes take

[2] The Pathology of Changes produced by Pressure in the Bony Skeleton of the Trunk and Shoulder Girdle: Guy's Hospital Report, 1885, 1886.

Digitized by Google

place in joints if the direction of force transmitted through them varies from the normal and the articulation is made to perform a function for which it was not originally fitted. I refer to changes occurring in the joints in knock-knee, bow-legs, lateral curvature, in cases of shortening of one leg by fracture or disease, &c. I am well aware that both rheumatoid and rheumatic arthritis, and especially the former, are very prone to affect a joint damaged in its anatomical detail, and consequently in its physiology, by occupation or injury, and this has been pointed out very clearly by Dr. Hensley of Bath, and it may in some few cases be difficult to state whether the condition is one whose causation is solely traumatic, or whether added to this we have in addition a factor whose mode of action is much more complex; yet I would assert that in the very large majority of instances of the condition which I have called chronic traumatic arthritis there is no difficulty in recognising it either clinically or in the dead body, and that therefore we should no longer include this definite group under a series of names which only serve as a cloak to ignorance, but give it a definite and explanatory title.

St. Thomas's-street, S.E.

OBSERVATIONS ON CERTAIN DISPUTED POINTS IN RENAL PATHOLOGY.[1]

BY A. G. AULD, M.D.

FIRST I shall describe what seems to be the true interpretation of the morbid changes found in the pia mater and in the skin, then certain lesions in the Malpighian bodies, and lastly I shall deal with some considerations based on anatomical data respecting the cause of the polyuria which is so constantly observed in the contracting form of Bright's kidney. I have been enabled, through the courtesy of Dr. Coats, to examine the pia mater of all brains examined in the Western Infirmary during a period of fifteen months. In each case the membrane was carefully hardened in Müller's fluid and alcohol, then dehydrated, and soaked for some days in Hamilton's freezing fluid A. From the resulting sections some valuable facts were obtained; and, in particular, I have been enabled to make out by means of high powers what seems to be the true nature of the hyaline-fibroid thickening of Gull and Sutton. As is well known, these authors, in their celebrated papers, contended that in Bright's disease the bloodvessels throughout the body, and especially those of the pia mater, had their outer coats thickened by the deposition therein of a hyaline fibroid material, probably derived from the blood. The muscular coat in such vessels they conceived to be atrophied, while the inner coat frequently, but by no means invariably, partook of hyperplastic change. This theory received a most damaging criticism from Johnson, who strongly maintained the truly hypertrophic condition of the muscular layer, while the so-called "hyaline fibroid" he alleged to be a delusive result of reagents, such as glycerine and acidulated mounting fluids. In 1873 Grainger Stewart pointed out that, while mounting media undoubtedly had some influence in producing the hyaline appearance, not a few cases exhibited a true fibrous thickening. Dickinson subsequently lent his adherence to this view, but the precise nature of the change is still the theme of debate. According to my observations, it may be stated generally that in Bright's disease all the coats are thickened. In the vast majority of cases the inner coat shows endarteritis. This change seems very constant in fatty kidneys in adults, though it is occasionally absent in contracting kidney. As regards the muscular coat, there can be no room for doubt that Johnson's contention is the correct one. Further, it was maintained by this eminent observer that a longitudinal layer of muscle-cells could be observed alongside the hypertrophied circular layer in some of these cases. It was asserted by Dr. Bryan Waller that this was an impossibility, and that Dr. Johnson mistook the cellular strata of the thickened inner coat for a layer of muscle cells. I think, however, that on looking at one of the specimens we will be satisfied that to the inside of the hypertrophied circular coat longitudinal muscular fibres exist which can in no way be confounded with the proximate layers of the thickened intima. There are, however, some cases in which the muscular hypertrophy is far from being a marked feature, and when the disease is far advanced degenerative changes of an aggressive character attack the hypertrophied fibres. In the case of the outer coat it is plainly shown from these preparations that it is thickened, and the question is, What is the nature of this thickening? Now, after eliminating the possibility of amyloid disease by careful staining, I have invariably made out by means of very high powers the existence of branched corpuscles, with dividing nuclei, either embedded in or lying alongside the hyaline-fibroid formation. It is clear that this formation owes its origin to a slowly progressing inflammatory new formation of connective tissue, and that the effect of reagents is, after all, but unimportant. Not only so, but this corpuscular activity is manifest throughout the connective tissue of the pia mater generally, leading to a more or less general thickening.

As regards the *skin*, the sections show that the muscular coats of the arterioles are much thickened. This is generally to be observed. In one case, in which the œdema was a very marked feature, the derma is unduly cellular; clusters of leucocytes seem to be scattered throughout its substance. It seems as though some inflammatory process were at work, and hence we find here considerable support to the view of Cohnheim as to the cause of this form of œdema.

With regard to the lesions of the kidney itself in chronic Bright's disease, examination of a large number of kidneys has led me to recognise two great divisions. In one, the lesions of the glomeruli and of Bowman's capsule are very marked, and overshadow the other lesions; in the other class the reverse holds good.[2] Greenfield recognises the lesions of the capsule as pericapsulitis or cellular infiltration and tissue-formation occurring chiefly outside this structure, as hyaline thickening of the capsule itself, and as endo-capsulitis or the formation of concentric laminæ of cells and tissue inside the capsule between it and the glomerular tuft. Greenfield regards the cells lining the capsule to be capable of originating this formation. Now, in acute glomerulitis it is undoubted that layers of epithelial cells are formed inside the capsule, derived from germination of its lining epithelium. But in chronic glomerulitis this is no longer seen. Instead we have the following changes:—1. The epithelial cells covering the glomeruli swell and assume a peg-top or columnar shape (well seen in the section placed under the microscope); they then fall into the periglomerular space, and assume a rounded form. 2. A similar desquamation of the cells lining the capsule occurs, but without the intervention of the columnar shape. 3. The connective tissue nuclei, and likewise the nuclei of the capillary walls of the Malpighian tufts, germinate, multiply, and give rise to a new growth of tissue between the capsule and the tuft, the capillaries undergoing hyaline thickening the while. In one specimen we see a band of new tissue stretching across the peri-glomerular space to which numerous epithelial cells have attached themselves—a phenomenon which has been questioned by Ziegler and some others. 4. Not infrequently the capsule itself becomes slit up into several layers, giving the appearance of two or more capsules for part of its circumference. This dissecting process is accomplished by cells from the surrounding connective tissue. In other and more advanced cases the capsule appears striated and concentrically thickened, and blends with the sclerosed glomerular tuft. It is difficult to see why these lesions should occur in some cases and not in others; they are by no means confined to scarlatinal cases, and, moreover, in post-scarlatinal nephritis which has assumed a chronic form they are occasionally absent.

Lastly, I propose to advance a few original considerations respecting the cause of the polyuria which is such a characteristic symptom of contracting kidney—considerations based, I may say, almost entirely on the histological appearances which this kidney presents. It is the universal custom to ascribe the excess of urine to one or other, or else a combination, of the following factors. Increase of the blood pressure generally; increase of the blood pressure locally in the glomeruli, arising from obliteration of capillary areas; inability of the tubular epithelium to absorb the water passing from the glomeruli; and increased permeability of

[1] A paper delivered, with microscopic demonstrations, before the Glasgow Pathological and Clinical Society, Jan. 11th, 1892.

[2] I purposely omit here particular reference to changes in the parenchyma.

Digitized by Google

the glomerular wall. On each and all of these alleged causes the facts of pathological histology seem to me to cast grave doubt. As regards the third of these—the inability of the glandular epithelium to absorb the water,—I do not believe that such an absorption normally occurs; for if it did, we should have the extraordinary phenomenon of a cell simultaneously secreting and absorbing a waste product. Many arguments could be adduced against this theory, but it does not vitally concern my position. Consider first the normal secretion of urine. It is accomplished by two great systems, from two great sources. One of these is the glomerular system, which secretes the watery part of the urine *plus* the salts; the other is the tubular system, which secretes a fluid rich in urea and extractives. This is conclusively proved by the experiments of Nussbaum on amphibians, and by the experiments of Heidenhain. With respect to the glomerular system, the view of Heidenhain seems unquestionably the correct one, that the Malpighian body is in reality a secreting gland and not a mere filtrating apparatus, otherwise it is inconceivable how, after section of the medulla, the injection of sodium acetate into the blood is accompanied by a copious secretion of urine which is of course unattended by any rise in the blood pressure. And, indeed, in the case of granular kidney, Broadbent has given cases in which the polyuria was marked without any rise in the arterial tension. The epithelium of the tuft is therefore pre-eminently a water-secreting epithelium. Now, what is observed on examining microscopically sections of granular kidneys? It is found that the glomeruli are agglomerated together in more or less wedge-shaped areas of sclerotic tissue, the intervening spaces being occupied by dilated tubules whose basement membrane has escaped much alteration, but whose vascular supply is abnormally abundant. Now, in the majority of cases, 80 per cent. of the Malpighian corpuscles in these sclerosed areas are totally functionless. How, on any pressure theory, can the few remaining tufts manage to secrete the large quantity of water which flows from the kidney, especially when, in addition, it is considered that the tubules from the patent glomeruli are not infrequently snared by the cirrhotic tissue? It seems to me that this view must be abandoned, and the seat of the secretion of water sought for elsewhere. This I believe to be found in a peculiar modification or transformation of the tubular epithelium in the areas which have escaped destruction. It is a remarkable fact, acknowledged by all observers, that the normal glandular epithelium in this situation becomes converted in granular kidney into a thin, flat epithelium—an epithelium, in fact, resembling that normally lining the glomerular tuft. This may be readily seen in the sections. Is there, therefore, any reason to deny that this peculiar modification of the epithelium is but a compensatory process of nature whereby the elimination of water is effected? Further, these epithelial cells have bright-staining nuclei which proves them to be in an active state. If it be not conceded that this epithelium actually subserves a modified function—that of secreting a much larger percentage of water than normally,—I think it at any rate cannot be denied that it more readily permits a passage outwards of water from the underlying bloodvessels, and that it ceases to become a "water-inhibiting" epithelium, as in the normal gland.

This view is supported by the anatomical appearances, by the constant diminution of the urine in cases where the epithelium is gravely injured, and by many of the kindred facts of pathology.

Glasgow.

CONGENITAL ANOMALIES OF THE RETINAL VEINS.

BY SYDNEY STEPHENSON, M.B., F.R.C.S. EDIN.

IT is impossible, I suppose, to over-estimate the importance of recognising congenital variations of normal conditions, and nowhere throughout the body does this recognition assume greater clinical consequence than in the eye. Loring[1] has well said, "It is the same old story of the musician and his scales. Five-sixths of the art of ophthalmoscopy are contained in a knowledge of the normal eye; the rest is a series of representations which can be read almost at sight." In the eye, as in other parts of the body, that arrangement of the vessels which obtains in the majority of cases is regarded as representing the normal condition of affairs. It may be well, therefore, to preface this account of certain anomalous dispositions of the retinal veins by a short description of the usual mode of distribution of these vessels. The primary division of the central vein of the retina may take place either in the retro-ocular portion of the optic nerve, or (less frequently perhaps) upon the surface of the disc itself. Either mode of division results in the formation of a superior and an inferior primary vein. These veins again divide (usually upon the disc), and their branches undergo division and subdivision in a dichotomous fashion; but it is commonly held that no inosculation takes place between the various branches. The whole process of repeated dichotomous division gives rise to the picture of an arborescent system of non-anastomosing veins, which, springing from the optic disc as a centre, ramify in the innermost part of the nervous tunic of the eye. The smaller variations observed in this general plan of distribution are innumerable: no two eyes ever present exactly the same arrangement of the retinal vessels. (The veins, it will be noticed, have been described as pursuing a course contrary to that taken by the blood current; this has been done simply for the sake of lucidity.) In accordance with the fact that, throughout the body generally, the arrangement of veins appears to be less stable and uniform, less fixed, so to speak, than that of the arterial system, one meets with anomalies of the retinal veins more frequently than of the retinal arteries. I have, for instance, seen eight examples of an anomalous disposition of the retinal veins during the past eighteen months; while during the same period I have failed to meet with a single anomalous retinal artery.

Turning now to the literature of the subject, one finds that the number of recorded cases is not great. In the *Medical News* (Philadelphia) of Sept. 11th, 1886, Dr. B. Alex. Randall published a case in which the central vein was connected with an aberrant vein by means of a cross-branch; the communication took place across the optic disc. The same author, moreover, recorded, in the Transactions of the American Ophthalmological Society for 1888, four new cases, and incidentally he mentioned the existence of a sixth case which he had recently encountered. Dr. Randall's communications are illustrated by drawings of the conditions he describes. In Vol. IX. of the Transactions of the Ophthalmological Society of the United Kingdom, Mr. Adams Frost, under the title of "Abnormal Course of a Retinal Vein," described a venous abnormality, which he had met with in the right eye of a young woman; while in Vol. X. of the same publication an account of "an abnormal retinal vein" is given by Mr. Louis Werner. Both these authors give pictures illustrative of their respective cases. Under the somewhat ill-conceived title of "Bifurcating Retinal Veins," I described, in Vol. XI. of the Transactions of the Ophthalmological Society, two examples of the condition in question. The patients were shown at a meeting of the Society; and illustrations of the anomalies will be found in the Transactions.

It appears, then, from the above catalogue that ten examples of the condition discussed have been placed on record. Accompanying this communication will be found sketches of six anomalous retinal veins which I have met with lately. In this number I do not, of course, include those cases mentioned above as having been shown by me to the Ophthalmological Society; for that matter, examples of arrangements similar to those then exhibited have been met with since, and are included among the sketches now presented.

In connexion with this matter of anomalous veins certain questions naturally present themselves. What forms do these anomalies assume? Are the arrangements seen reducible to any sort of order; or are they, on the other hand, wholly irregular? Judging from my own cases and the cases placed on record by others, I should say that the anomalous arrangements fall into one or other of three classes, with this reservation, however: that the classification here outlined must, in the absence of more extended observations, be regarded as more or less provisional in its nature. The first class includes cases in which two of the primary veins are united by

[1] Text-book of Ophthalmoscopy.

Digitized by Google

a cross-branch, or cases—and this obviously is to all intents and purposes the same thing—in which a branch connects a central with an aberrant vein. The first of these conditions is depicted in plates Nos. 4 and 5; while the second is shown in plate No. 3. Frost's case, alluded to above, belongs, I think, to the former division; and Nos. 4 and 5 in Randall's series afford good examples of the latter condition. The second class comprises cases in which a vein bifurcates while on its way to the centre of the disc. As shown in plate No. 2, the bifurcation may take place in close proximity to the axis of the papilla; or it may, on the other hand, as shown in plate No. 1, occur when the vein is still at a considerable distance from that point. As belonging to the second of these varieties I would class Randall's cases Nos. 1 and 2; while my own cases, which were shown at the Ophthalmological Society, afford examples of both the varieties described. The third class comprehends those cases in which a venous anastomosis is formed upon the disc itself. This, it appears, may be constituted in one of two ways. In the first case, by a vein dividing at the margin of the papilla into two branches, which, after forming a considerable circle, unite to enter the disc as a single trunk. Some or all of the veins may unite with this venous circle. In the second case one sees upon the optic disc a horseshoe-shaped vein, which, entering the papilla by its upper and lower extremity, receives the other retinal veins at various points in its course. I am not in a position to adduce an example of the first variety; Randall's plate No. 3 is, however, a case in point. The picture No. 6 will render clear the nature of the second variety, and Werner's case, also, appears to come within this category.

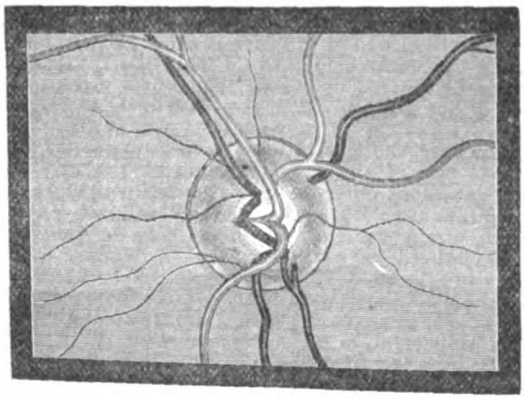

FIG. 2.

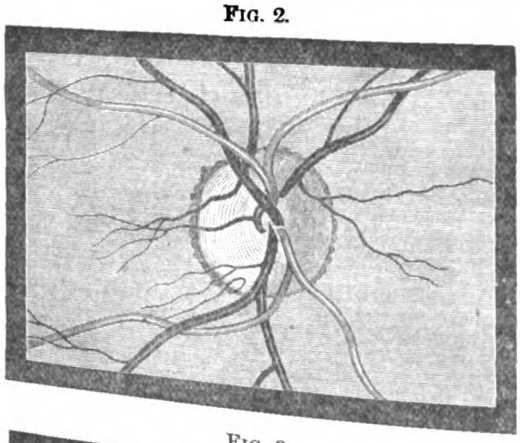

FIG. 3.

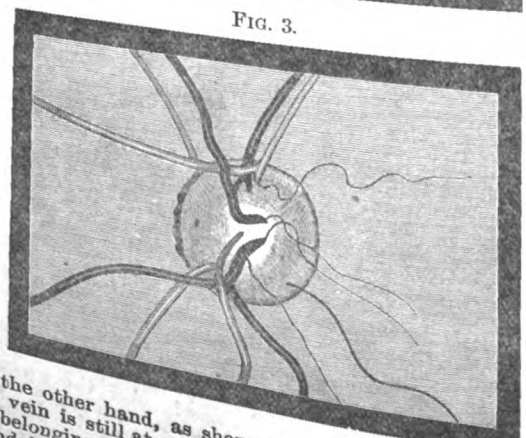

FIG. 4.

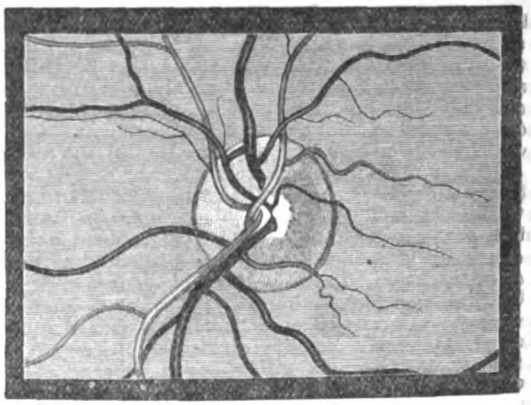

FIG. 5.

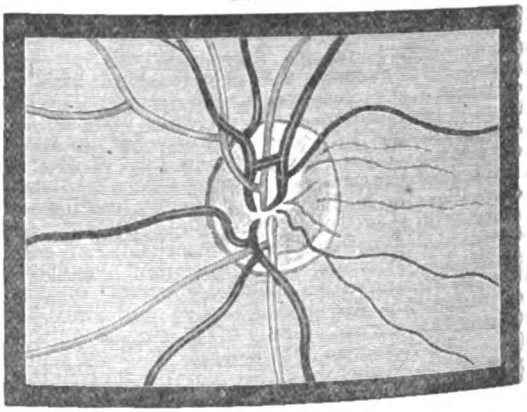

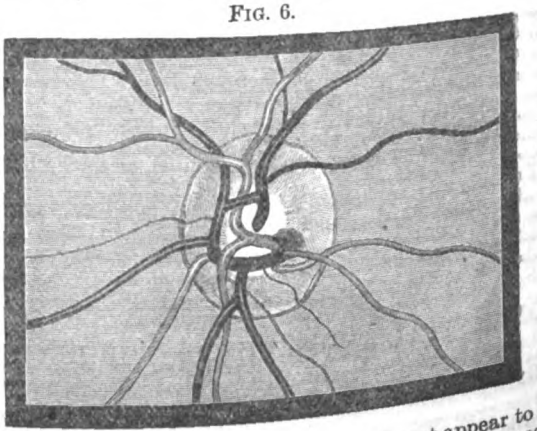

FIG. 6.

These anomalous venous arrangements do not appear to be associated with systemic abnormalities—at least, in no case has any such conjunction been noted. Furthermore, it is worthy of mention that in all the recorded cases the anomaly has been limited to one eye. Whether the explanation of these anomalies be connected with the repetition of conditions natural in the eyes of some of the lower animals, or whether, as seems perhaps more probable, the persistence of fœtal conditions has more to do with the matter, I am

Digitized by Google

unable to say. One knows, however, that many of the variations from the normal observed in the bloodvessels generally receive their explanation in some such way, and there appears to be no valid reason why the vessels of the eye should furnish any exception to the rule. Be this as it may, it becomes of some practical importance to know that anomalies of a purely congenital nature are not very uncommon in the veins of the human retina. Out of every 1000 eyes examined I estimate, indeed, that at least three will show an anomalous arrangement of the retinal veins.

Ophthalmic School, Hanwell, W.

CASE OF HERPES OF THE LARYNX.

BY R. E SCHOLEFIELD, M.A., M.B.,
RADCLIFFE TRAVELLING FELLOW, OXON.

THE following case, which came under my notice during my admission period at St. Bartholomew's Hospital, from the curious character of the symptoms presented and the difficulty of finding an explanation for the same, may be of interest to the readers of THE LANCET, though I venture to think the case is anomalous.

S. A——, forty-one years of age, packing-case maker, came, or rather was brought, to the hospital by a fellow-workman on Nov. 18th last, suffering from a curious combination of dyspnœa, difficulty in swallowing, and nervous excitement. The history of his condition was that he was in good health up to about a fortnight previously, when he had a slight bilious attack with giddiness, which, however, did not prevent him from following his occupation. A similar attack occurred again a few days before admission.

On Nov. 17th the patient first felt a "tightness" in his throat, with some hoarseness and cough; he continued at work, however, till the 18th, when in the afternoon his throat became so much worse that he had to be brought to the hospital. He complained of intense pain on swallowing, with a difficulty in getting his breath, and a feeling of tightness about the throat. The patient presented a most curious appearance: he sat with a face expressing the utmost anxiety, his eyes seeming to protrude, swimming with tears, which ran down his face, his mouth was open and the saliva ran in large quantities over his lip down into his beard. The alæ nasi and lips appeared red and slightly swollen. The dyspnœa was not very marked, but his breath was drawn with fear and trembling. The most remarkable feature of the case, however, was that when he attempted to swallow, not only his face but his whole body writhed with agony, almost resembling a convulsion, and he had evidently the greatest dread of making the attempt. He spoke in a hoarse whisper, and not more than was absolutely necessary; but on pressing him to do so I found that phonation was not only possible, but was not even distinctly impaired. He complained of great pain on the left side of the neck, and pressure anywhere between the left side of the larynx and the ear was not only extremely painful, but also caused him to roll about in the most extraordinary contortions. One's first thought was of hydrophobia, but no evidence could be obtained in the least supporting this view. The man was certainly not in liquor, as his habits were most temperate, and his companions vouched for the almost sudden onset of the condition while at work. Family and personal history threw no light on the subject. He was temperate, married, family healthy, and had never had syphilis. External examination was equally negative, except that the glands on the left side of the neck were slightly enlarged, and the tenderness over them was extreme. On examining the mouth, the fauces were slightly reddened and the uvula somewhat œdematous, but there was no great tenderness and no sign of membrane or ulceration to be seen; clear and glassy mucus was, however, standing everywhere in beads, and pouring rapidly from the naso-pharynx. His temperature was 103·4°; pulse 116, weak; respiration 25, drawn apparently rather with a sense of pain than with a desire for air.

With some difficulty I was able, after the use of cocaine to the fauces, to make a perfectly satisfactory laryngoscopic examination, which disclosed the following. The cords and ventricular bands were perfectly normal, as also was the right arytenoid and aryteno-epiglottic fold. The left, however, was redder than natural, and presented a mass about the size and shape of three peas more or less fused together, and capable of being moved over with a probe either to the laryngeal or œsophageal side of the ary-epiglottic fold, to the edge of which they were attached. The surface was redder than natural, quite smooth, and glistening like that of a polyp or a polypoid degeneration of the mucous membrane, for which I at first took them. Posterior rhinoscopy revealed nothing further. From their position and displaceability they were, granting their tenderness, capable of creating the greatest trouble either in phonation or in swallowing, as, when the epiglottis was depressed in the latter case, they were pressed into the pharynx, while in the former they somewhat overhung the orifice of the larynx, the entrance or exit of air through which caused them to vibrate enough to produce pain. Of their real nature I had then no idea.

He was admitted, and an ether draught administered, with cold compresses to the neck. During the night he was most restless, taking only a little milk, and that with great pain and difficulty, expectorating about one pint of thin mucus, which was free from odour.—Nov. 19th: Condition slightly improved. Temperature 99·3°. Voice more natural; still great difficulty in swallowing. Urine: sp. gr. 1028; no albumen or sugar. No signs of disease in chest or lungs. The laryngoscope showed the tumour—if it may be called such—about the same, except that it was of a more milky colour, and there was more general swelling of the arytenoid, the right being also somewhat enlarged.—20th: Condition much improved in all respects; though still much pain on swallowing, there are none of the nervous symptoms with it. Temperature 98·6°. The condition now is that of a small bulla, filled apparently with pus, seated on the summit of the enlarged and swollen arytenoid. A patch of herpes was now observable, beginning about the left nostril and upper lip.—21st: Condition still improving. Temperature subnormal now. The bulla has now disappeared, and its place is occupied by a white patch of macerated epithelium, which could not be removed with a probe. Arytenoid not so much swollen. Herpes on lip and alæ nasi more extensive, and spreading to the other side. During the next few days he improved much in general health; pain on swallowing gradually disappeared, as also did the white patch and the swelling on the arytenoid. The voice became quite normal. The herpes on the lips and alæ nasi went through the ordinary stages of that eruption. It was rather extensive, passing up a little into the nostril. On Dec. 3rd the man was discharged with the herpes healed and the larynx normal.

It needs only to be remarked that I regard the case as one of buccal herpes, peculiar chiefly in the seat of the first vesicles, which were what I took for a polypoid growth; their course, however, through the milky to the purulent stage, bursting and then leaving a base which, becoming macerated by the saliva, looked like a white patch, points to this explanation. The pain in the neck, most marked at the onset, subsiding earlier than the eruption, the salivation and the rapid fall of the initial temperature, all confirm this view. I have since seen a case of herpes of the face and soft palate in which, though great pain was absent, the temperature and constitutional disturbance ran a similar course, being 103° when first seen, falling to normal on the third day, when the eruption showed itself. I hope that the case may not be without interest to the profession. It was certainly, to begin with, most puzzling; for though herpes of the palate, tongue, and cheeks is, I believe, not very rare, I can find no reference in the text-books to its attacking the larynx. I must, in conclusion, thank Mr. Howard Marsh for his kind permission to publish the case, which was under his care.

OCCLUDED OS AT FULL TERM.

BY L. NASH, L.R.C.P. & S.ED.

I WAS much interested in reading in a recent number of THE LANCET of a case of occluded os at full term. As so few instances have been recorded, I think it may be worth while giving brief notes of two such cases occurring in my private practice whilst I was in Sindh.

CASE 1.—In May, 1890, I was called to a multiparous

Digitized by Google

Hindu woman, who had been in labour about two days. At the end of that time the native midwife gave it as her opinion that the woman would never be delivered, and left her. When I arrived the patient was having pains. On examining, my finger met a smooth elastic wall, with no trace of cervix or os. It was puzzling; but after some time, carefully feeling round, I detected a slight dimple where I should expect the os to be. The pains occurred at intervals, but, beyond stretching the uterine wall, did nothing to dilate the closed os. The head was not fixed. Between the pains I gently scratched with my nail, and the tissue yielded with some very slight bleeding until I encountered the membranes, which were adherent round the os. These I cleared, and they began dilating, but the process was slow, partly because the parts were rigid with what felt like cicatricial tissue and also because the pains were becoming feebler. When the head had fixed I ruptured to relieve the uterus and assisted dilatation with my fingers, and finally put on forceps, delivering a live child, who, however, required resuscitation. The patient declined further European treatment, but eventually did well.

CASE 2.—In September, 1890, I was called one evening to a multiparous Mahommedan woman, who had been in labour over twenty-four hours. The waters had been dribbling away all day, but no progress was made. On examining, my finger met the same smooth fleshy sphere, all trace of the cervix being gone; but in this case there was a slight roughness indicating the site of the os, and the cicatrix was more readily torn through, there being no bag of membranes (I could not detect the aperture through which the waters had escaped). On rupturing meconium escaped. The face was presenting and had fixed. I gave the girl an opiate, as the moulding being insufficient forceps failed to deliver. Early next morning pains returned, and the patient was safely delivered of a stillborn well-formed boy. The mother did well eventually, but was much exhausted for some time, owing to the unhealthy surroundings and long-standing anæmia.

It is said that occlusion of the os generally occurs in primiparæ. It may be so amongst Europeans. I should think the probable cause in both these cases was due to the treatment either after previous delivery in the Hindu and during pregnancy in the Mahommedan by the *dhais* or native midwives, amongst whose gynæcological customs it is to pass native uterine sounds to induce a condition fit for pregnancy, and to fill the vagina with boluses made of treacle and herbs.

ST. MARY'S HOSPITAL.

A CASE OF UNRECOGNISED CERVICAL CARIES; REMARKS.

(Under the care of Mr. EDMUND OWEN, F.R.C.S.[1])

IT is most important to recognise disease in the cervical region of the spine early, as the ultimate success of any treatment undertaken will depend almost entirely on the stage at which the disease has arrived when this treatment is commenced. It is not very unusual to meet with cases of cervical caries in the out-patient department of a children's hospital, in which the patient is said to be suffering from "a stiff neck," "cold in the neck," or rheumatism. It is, however, much more unusual to meet with advanced disease at the age of this patient, for the severity of the pain compels the sufferer to seek efficient medical relief. The account of the case is very instructive.

A. D——, a Welsh servant-girl of nineteen years, was sent to St. Mary's Hospital on May 29th last by Dr. Edward Lewis of St. John's Wood. Of her sixteen brothers and sisters only six are living. On her arrival she appeared pale, delicate, and distressed. She said that she had been in service in London, and that for a long while she had suffered from severe "headaches," chiefly at the top of her head, for which no clear explanation was given nor available treatment found. One medical man told her that London air did not suit her, and that she had better go back to Wales. Others attributed her pains to "rheumatism." She had taken a large amount of medicine, but nevertheless she had got steadily worse, and had at last to give up work entirely. Dr. Lewis wrote that he had seen the girl at a patient's house where he was visiting; the lady asked him to examine her, because she thought that she was too ill to take so long a journey as to Wales. She had been attending as an out-patient at a general hospital for three weeks, and the day before Dr. Lewis's seeing her—such was her story—three medical gentlemen at the hospital had consulted over her, and had pronounced her disease to be rheumatism. Dr. Lewis, recognising not only the existence of cervical caries, but also of a post-pharyngeal abscess, sent her at once to St. Mary's Hospital. Without doubt the girl was extremely ill, and she had, moreover, the aspect of one who was suffering greatly. She could not bear the least pressure upon the top of her head. She held her neck very stiffly, and she could not turn her head without at the same time wheeling round her body, nor could she nod her head. When closely questioned as to the exact parts in which she felt pain she pointed out the areas of distribution of the branches of the great occipital division of the second cervical nerve, and of all the branches of the superficial plexus—the lesser occipital, the great auricular, the transverse cervical, and the twigs of the supra-clavicular nerves in the sternal, pectoral, and deltoid regions. But of all these nerves the great and the lesser occipital were those chiefly distressed, which fact showed that the inflammatory disease of the spine was most advanced in the first and second vertebræ, the second cervical nerve emerging between the atlas and axis previous to giving off the two occipital branches.

Forthwith she was placed flat on her back in bed, a thin, narrow cushion was adjusted beneath her neck, and her head was steadied between two large sand-pillows. The same evening Mr. Farquharson, the house surgeon, opened the post-pharyngeal abscess, much to the temporary relief of the patient. Indeed, for a time she greatly improved; her neuralgias diminished, and, with the advantage of this absolute rest, she gave some hope of recovery. But the pains persisted in considerable degree, and, dreading the least shake or disturbance, she generally lay with her hands up to her aching head. On her admission the temperature was 101°, and during the remainder of the time varied between 99° and 102°. Towards the end it was generally 102° at night and 99° in the morning, she being hectic. She gradually grew weaker, Cheyne-Stokes breathing occurred—the result of pressure upon the medulla,—and she died on Nov. 11th, after several days of complete unconsciousness.

Necropsy.—As the body lay upon the table the attention of the pathologist, Mr. J. J. Clarke, was at once drawn to a marked prominence of the spinous process of the axis. This prominence showed that the transverse atlo-axoid ligament had given way, that the occiput and atlas had been carried forwards, and that the back of the odontoid process pressed against the top of the spinal cord. This, indeed, was the case, an antero-posterior section of the parts showing that a space of half an inch existed between the anterior arch of the atlas and the odontoid process, with the result that the spinal canal behind it had been diminished to an equal extent, so that the odontoid process was thrust against the cord. There was a considerable collection of pus about the atlas and axis, and an opening in the posterior wall of the pharynx showed where the abscess had been originally evacuated. There was, moreover, purulent and tubercular infiltration about the third and fourth vertebræ, the membranes of the cord in the upper cervical region being greatly thickened. Thus pressure was exerted upon the first four cervical nerves not only by purulent infiltration, but also by the thickened dura mater which formed their sheathes.

Remarks by Mr. OWEN.—In some quarters the terms "rheumatism" and "rheumatic" are apparently of very wide signification, their comprehensiveness often being their chief recommendation. The first meaning of the word ῥευματικος is, we are told, a *flux*, or *looseness*—a looseness of diagnosis being, no doubt, included. This is not the time or place for showing how often, amongst other things, the acute ostitis and periostitis of childhood are treated as "rheumatism"; but it

[1] Reported to the West London Medico-Chirurgical Society, Jan. 8th, 1892.

Digitized by Google

may well be made the occasion of insisting on the fact that the peripheral neuralgias of spinal caries are constantly being misunderstood. The most suggestive feature of the pains of central spinal disease is their symmetrical arrangement. Thus, in the girl whose case is under consideration there was pain in the areas of distribution of the nerves on each side of the head and neck, and over both pectoral and deltoid regions. In lower cervical disease there may be pains in both arms, both elbows, or both hands. And so also with the symmetrical pains in the chest, abdomen, thighs, legs, and feet. In the case of another girl under treatment for lumbar caries, the only parts in which she complained of pains were the balls of the great toes—that is, at the terminal distribution of each long saphenous nerve. She must have run considerable risk of having her neuralgias ascribed to rheumatism, if not to gout. In conclusion, it may be insisted on that rheumatic and gouty pains lack the anatomical precision and symmetrical arrangement which characterise those of tubercular disease of the spine. Still, if a mistake must be made, it is for the greater good of the greater number of patients that rheumatism be taken for spinal disease rather than that spinal disease be regarded as rheumatism. The former error is more inconvenient than harmful, whilst the latter may prove not only an irremediable calamity, but might be reckoned a stupid blunder.

SAMARITAN HOSPITAL FOR WOMEN, BELFAST.

THREE INTERESTING CASES OF ABDOMINAL SECTION.

(Under the care of Dr. W. K. MCMORDIE.)

THESE three cases present some point of importance which makes them worthy of record. With regard to ovariotomy during pregnancy, the opinion of Mundé[1] is, "that so far as the chances of recovery from ovariotomy are concerned, they are fully as good as when no pregnancy exists. As regards the continuance of gestation, in the early months usually the prospect is also favourable. In the later months, when the child is viable and likely to survive, the induction of premature labour would appear to be preferable, with subsequent ovariotomy.

CASE 1. *Removal of an ovarian cyst, complicated with pregnancy.*—E. J——, aged thirty-four, married, was sent as a private patient to the Samaritan Hospital by Dr. Clarke of Portadown on Nov. 4th, 1891. She was married on Feb. 13th of the past year, and as the abdominal enlargement appeared shortly afterwards it was believed to be pregnancy. At the time of her admission the abdomen measured forty-eight inches round the umbilicus. A vaginal examination showed the uterus to be enlarged; but it was impossible to be certain of the cause. The uterine enlargement was not sufficient to account for pregnancy occurring about the time of her marriage, and so, if pregnancy existed, it must have occurred after the ovarian cyst had been growing for some time. The patient was not examined with the sound. At the operation the tumour was found to consist of one large cyst with thick wall, containing eighteen quarts of thick dark fluid and seven pounds solid. The uterus was enlarged to about the size of a fœtal head, and was evidently pregnant. The tumour was of the right ovary, and the left ovary was healthy. The uterus was in no way injured at the operation, and the fœtus was not afterwards expelled. There is no reasonable doubt but the pregnancy will go to full time. She made an excellent recovery.

CASE 2. *Large ovarian cyst tapped thirteen times in fourteen months; escape of cyst fluid into abdominal cavity; chronic sepsis after tapping; ovariotomy.*—J. M——, aged thirty-nine, married, had one child eleven years ago, was placed under the care of Dr. McMordie by Dr. MacArthur of Grey Abbey on Sept. 22nd, 1891. The following is the history of the case. She stated she first noticed the abdominal swelling eighteen months before in the right side. For fifteen months she had been under medical treatment. During that time she had been tapped thirteen times—eleven times by her family doctor in the country, and twice by a Belfast physician, on Aug. 29th and Sept. 18th, 1891. No means of ascertaining the measurements of the abdomen after each tapping were found. On Sept. 22nd—four days after the last tapping—the abdomen measured 32 in. round the umbilicus; on Oct. 1st, 33½ in.; Oct. 3rd, 34¼ in.; Oct. 12th, 38 in.; Oct. 16th, 39 in.; Oct. 19th, 40 in. The fluid was evidently rapidly increasing. There were symptoms of chronic sepsis; temperature above normal, quick pulse, and increasing feebleness. It was thought better to wait no longer, but to give her a chance of relief. Assisted by Dr. Henry O'Neill and by Dr. David McKinney acting as chloroformist, ovariotomy was performed by Dr. MacMordie on Oct. 21st. At the point where the cyst was opened it was adherent to the abdominal wall. When the contents had nearly all escaped the opening was enlarged and the hand passed into the cyst, the wall of which was very thin. A large opening in the cyst wall was found towards the diaphragm, through which the intestines were protruding. It was clearly through this opening the cyst fluid had escaped into the abdominal cavity, at which of the tappings it would be impossible to say, but more likely at the last, when the cyst, being only partially filled and the cyst wall more or less collapsed, would most likely receive a double wound from the trocar, and the sudden escape of the cyst fluid under pressure into the abdominal cavity through a very thin and friable cyst wall would increase the hole into a rent. The intestines soon appeared at the abdominal incision, and were with difficulty kept back. Lying towards the left side were three smaller cysts, containing bloody, friable, solid material, which weighed six pounds. The pedicle was broad and thick, and required to be ligatured in three parts. The abdominal cavity was carefully washed out and a drainage-tube left in. Through the tube the abdomen was carefully washed out daily for five days. The case made favourable progress until the seventh day, when the heart's action suddenly failed, and she died at a time when everything seemed to point to a favourable result.

Remarks by Dr. MCMORDIE.—The interest in this case consists in the extraordinary number of tappings in so short a time and the escape of the cyst fluid into the abdominal cavity. Among the symptoms of exhaustion noted before the operation were the low specific gravity of the urine and feeble action of the heart. It is a reasonable conclusion to come to from all the facts of the case, that had the ovarian tumour been removed before the frequent and persistent tappings, a favourable result might with confidence have been anticipated. Another point of some interest is that at none of the tappings could there have been complete collapse of the abdominal tumour owing to the presence of so large a quantity of solid. I have reported in every detail this case, in the hope that a knowledge of the consequences that may result from tapping may act as a warning to other operators.

CASE 3. *Tubo-ovarian abscess caused by septic infection after labour, treated by abdominal section; recovery.*—E. McG——, aged thirty-three; had three children, the last one seven months before her admission to the hospital on June 2nd, 1890. On the third day after her confinement she had a rigor and a severe pain in the right ovarian region. She was sent to hospital by her family physician, Dr. Humphries of Mountpottinger. On her admission the temperature was 103° F. An examination revealed a smooth, round, movable lump deep in the right ovarian region. No fluctuation could be detected. With complete rest the pain disappeared, but the high temperature continued, and she got very weak and much emaciated. For some time she would not consent to any operative interference. On July 15th the usual incision was made in the median line. The tumour was covered with intestine and omentum, dipped deep into the pelvis, and was adherent to the intestines. The wall was thick. So firm was it bound by deep adhesions that it was impossible to get more than a small portion of the circumference out of the abdominal incision. A trocar was inserted, and a pint of thick, fetid pus drawn off. The cyst wall was like leather, but it was so firmly held down at the lower part that it was impossible to draw it sufficiently up to apply a ligature at the base. To have done so a much larger abdominal incision would have been required, and more manipulation of the intestines would have been the result, which in the weak and exhausted condition of the patient would have added much to the risk of the operation. The cyst cavity was therefore washed out and the edges sutured to the lower angle of the abdominal incision. A drainage-tube was left in and the cavity daily washed out. The cavity steadily contracted, and the tube was removed at the end of a week, when only a sinus remained. This gradually closed, and she was discharged on Aug. 18th in good health. At the operation, Dr. McMordie was assisted by Dr. Henry O'Neill, and the anæsthetic was administered by Dr. D. McKinney.

Medical Societies.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Recent Researches in Diabetes Mellitus.—Inflammatory Cervical Swelling communicating with Common Carotid Artery and Internal Jugular Vein.

AN ordinary meeting of this Society took place on Jan 26th, the President, Mr. Timothy Holmes, in the chair.

DR. HENRY J. TYLDEN communicated a critique on Recent Researches in Diabetes Mellitus, with an original note on the pathology of the pancreas. Three lines of recent research promised to throw new light on diabetes: M. Lepine's glycolytic ferment in the blood; certain experiments which had been undertaken on the pancreas; and a renewed study of the morbid histology of the pancreas. The object of this paper was to describe some of the more important of these researches, briefly to criticise their methods, but still more to offer some criticism upon the inferences which were being drawn from them. With regard to M. Lepine's work on the glycolytic ferment of the blood, his methods were described. Granting the existence of this ferment in blood drawn from animals, was it a vital phenomenon? The question could not be considered as settled, but there were grounds for supposing that it probably was. He asked if the diminution of this ferment in diabetes could be regarded as the cause of the disease. To this he advanced the following objections: 1. Perhaps all ferments were reduced in wasting diseases. 2. Certain clinical facts warranted us in supposing that diabetes was due, not so much to failure of sugar-destruction as to increase of sugar-production in the system. As to the recent experiments on the pancreas, extirpation was found to be followed immediately by diabetes mellitus. Partial extirpation, injection of the pancreatic duct with irritants and tying of the pancreatic vessels; none of them produced permanent glycosuria, but led to cirrhosis of the pancreas, and were followed by azoturia, polyuria, and wasting. He asked if the glycosuria which followed upon complete extirpation of the pancreas was a result of the removal of the pancreas, or of some lesion incidental to the operation, and he thought that, while there were difficulties in the way of either interpretation, probably the latter was the true answer to the question. Dealing with the morbid histology of the pancreas, he said that cirrhotic changes had been demonstrated in diabetic pancreases, and no doubt correctly; but before we accepted them as the cause of the disease we must ask ourselves the following questions: 1. Was the lesion constant in diabetes? It certainly was not, some diabetic pancreases showing no departure from the normal in their histological characters—certainly none in the direction of cirrhosis. 2 Was it confined to diabetes, or had it wider relations with sundry other diseases? A microscopical examination of some fifty pancreases led to the recognition of two forms of cirrhosis at least—the one coarse and interlobular, often seen in very wasted pancreases, the other finer and intercellular in pancreases not necessarily wasted. The latter form had been found to occur chiefly in patients who were the subjects of granular kidney. It was possible that the pancreatic change might throw light in some cases of chronic Bright's disease upon some of the symptoms of the disease, especially when we remembered that polyuria and wasting were two of the results of artificial cirrhosis of the pancreas. 3. Assuming the first two points, had we any reason to suppose that cirrhosis of the pancreas would, even if present, provoke glycosuria? As far as we knew we had not; experiments went to prove the contrary. As we could not answer one of the questions in the affirmative, we could not accept either the pancreatic hypothesis of diabetes or M. Lepine's form of it.—Dr. GEORGE HARLEY said that the Society was much indebted to the author for an admirable paper. Many seemed to hold the belief that pancreatic diabetes was a newly discovered disease, but Dr. Thomas Corley had published a case in a London medical journal in 1788, and since then many had been placed on record, though their importance had not been fully appreciated until the advent of the experimental pathologist. Many people seemed to think that diabetes in all cases had a similar pathology, and the author appeared to share this opinion. He was sure that this notion was erroneous, and that glycosuria was simply a sign of disease and might own various causes, as was the case with albuminuria. Injury to the fourth ventricle, a blow on the back of the head, disorder of the liver, all might act as causative agents, as well as pancreatic disease. It was difficult to believe that if total extirpation of the pancreas brought about diabetes, ligature of its vessels would not bring about a like result. Von Mering had isolated the pancreas in the dog from all its attachments except the vessels, and no diabetes had been produced by that procedure. He held that there were two essential kinds of diabetes—that caused by excessive formation of sugar in the blood, and that produced by diminished destruction of sugar—and that the two were not comparable. He held also that atrophy of the pancreas produced glycosuria, and he thought that until a better theory was promulgated Lepine's hypothesis should be accepted.—Dr. ROLLESTON said that any change in the pancreas in association with diabetes could not be regarded as a prime cause of that disease. It was said that if three-fourths of the pancreas were removed no diabetes would result, because sufficient ferment would be produced in the portion left. On this hypothesis blocking of the duct ought to produce diabetes mellitus, because as a result of the tension produced by ligature of the duct absorption of the secretion by the bloodvessels ought to take place. He had seen this duct completely blocked by a calculus, and yet no diabetes result; on the other hand, in a case of marked diabetes he had seen the organ weighing four ounces and of remarkably healthy appearance. In one instance there was such a marked cirrhosis of the organ produced by the pressure of an aneurysm that its structure was so disorganised that it could not be recognised microscopically, and yet diabetes was not present; cases, too, had been recorded in which there were abscess and sloughing of that organ unaccompanied by glycosuria. The polyuria which accompanied the cases in which there was both cirrhosis of the kidney and of the pancreas was much more easily explained in other ways. He thought that any severe disease attacking the pancreas might reflexly so stimulate the medulla as to produce increased metabolism of the liver with resulting diabetes.—Dr. BRADFORD said that there was no fact in recent experimental pathology more clearly made out than the effect of operations upon the pancreas in producing glycosuria. Minkowski at Berne removed seven-eighths of the pancreas from a number of dogs, and no abnormal result followed. He then removed the small fragment which was left, and marked glycosuria was produced. It was idle to suggest that this phenomenon was produced by other lesions in the neighbourhood of the pancreas, for other physiologists had damaged all the structures in the neighbourhood of the pancreas, leaving that organ intact, and still no glycosuria was produced. Minkowski's conclusions were borne out by analogy, for if very large portions of the thyroid were removed, nothing abnormal would happen; whereas if the small remaining fragment were taken away, death would result. If half of one kidney were removed no marked change would be noticed; but if the whole of the other organ were then taken away a widespread disturbance of nutrition would result, wasting, polyuria, and increased secretion of urea being the most marked sequelæ. Ponfick had also demonstrated practically the same thing with regard to the liver. Although physiologists were not at present able to satisfactorily explain these results, yet they showed in a striking way that organs had functions which at first sight they were not credited with. He was of course prepared to admit that diabetes was a symptom, and not a disease. Finally, he referred to two cases which had been under his own care. One was a man who suffered with diabetes mellitus and ascites; at the necropsy a large primary growth of the pancreas was found. The second case died of diabetic coma; he pancreas weighed under an ounce, and was much cirrhosed.—Dr. TYLDEN, in reply, defended himself from certain criticisms that had been made concerning his paper. He did not contend that diabetes was a simple disease; for aught he knew it might depend on many causes. His argument was a twofold one: that in some cases of diabetes mellitus pancreatic change was absent, and also that marked pancreatic change might be present without glycosuria. As to the diverse results following removal of the pancreas and ligature of its duct respectively, he simply stated recorded facts without attempting to explain them.

Digitized by Google

Though he was not prepared to accept Lepine's theory, he was far from saying that he rejected it; the evidence to justify the latter course was not yet nearly strong enough. Finally, he felt no moral obligation to accept the best hypothesis in the field, and, while he agreed with most of Dr. Bradford's arguments, he could not allow that the analogies proposed helped to remove the difficulty.

Mr. CROFT read the details of a case of Glandular Swelling in the Neck, which became converted into a pulsating tumour-like aneurysm; the common and external carotids and the internal jugular vein were ligatured. The author first narrated the particulars of the case. A young man aged twenty-two was admitted into St. Thomas's Hospital, under Mr. Croft's care, on June 4th, 1891. A small swelling had appeared on the right side of the neck, opposite the thyroid cartilage, after sore-throat, about eight weeks before his admission. This swelling became rapidly larger a week before he applied to the hospital. At the time of admission the swelling was about as large as a pullet's egg, and was situated over the bifurcation of the common carotid. It was examined for pulsation, but none was observed. During the evening of the second day the swelling rapidly enlarged, and this was accompanied by fresh pain and a little difficulty in swallowing. The next morning the tumour was found to be strongly pulsatile, with distinct expansile movement. Mr. Croft saw the patient on this day (the third), June 8th, and decided at once to explore the swelling. The diagnosis presented considerable difficulty. The common carotid trunk below the swelling was first exposed; next the swelling was incised, and shown to be in communication with a large artery. It was found necessary, in order to arrest all hæmorrhage, venous and arterial, to tie the common and the external carotid arteries and the internal jugular vein. No pus was found or any definite abscess. The operation was performed throughout with careful antiseptic precautions. Carbolised silk ligatures were employed. Recovery was complete, though complicated by congestion of the left lung. The ligatures remained buried in the wound. The nature of the morbid action was briefly discussed. The other point adverted to was the immediate and permanent abolition of the inflammatory process, with its destructive tendencies, although no collection of pus or any inflamed glands had been removed.—The PRESIDENT remarked that the case recalled forcibly one placed on record by Liston, in which the patient lost his life in consequence of having a collection of pus opened in the neck without it being ascertained that it communicated with an artery. Mr. Croft's case showed how possible it was for inflammatory softening to cause giving way of vessels at a particular moment, and it illustrated the old surgical adage that suppuration around a vessel might lead to communication with that vessel. He himself had seen a case in which a large swelling of the ham was punctured, and the abscess communicated with the popliteal artery. In Mr. Croft's case no pus was seen, but it was possible if a small quantity were present it would be masked by the larger quantity of blood contained in the swelling. He believed that there were as many as twenty cases on record in which the common carotid artery and internal jugular vein were tied simultaneously.—Mr. BARWELL dilated on the possibility of the swelling being really an abscess. There was fluctuation previous to the commencement of pulsation, and this fluctuation must have been due to a fluid collection. As the case was inflammatory, he thought the fluid was probably pus, and this might have been very readily carried away in the blood stream without inducing symptoms; so that not seeing pus at the time of opening did not militate against its being an abscess. He inquired why such stress was laid upon the use of silk ligatures.—Mr. CROFT, in reply, said that as to the question of pus being present he certainly did not see any. The origin was inflammatory, and whether the inflammation ended in pus-production or in exudation short of that did not matter; the pathological destructive process was equally effective. He was not at all prepared to agree that if pus entered the arteries or veins no harm would ensue; but it was a fact that from the moment the operation was completed, and the pneumonia recovered from, the patient became convalescent. He did not think that such a result could possibly have occurred if pus had got into the veins. He preferred a silk ligature because it was more durable than catgut or kangaroo tail; it was thoroughly reliable, and caused no irritation when properly prepared and buried in the wound.

MEDICAL SOCIETY OF LONDON.

Compound Fracture of Skull in Children.—Bronchiectasis in Children.—Plastic Operations for Contracture following Burn.—Syringomyelia.—Sarcoma in Association with Multiple Exostosis.—Primary Chancre of Cheek.

A "CLINICAL" meeting of this Society took place on Jan. 25th, the President, Dr. Douglas Powell, in the chair.

Mr. J. H. MORGAN brought two children who had suffered Compound Fracture of the Skull. The first was a boy aged two years, who fell from a window on the third storey, alighting on his head. He was admitted within a few minutes to Charing-cross Hospital. He was conscious, there was no paralysis, but the pupils were dilated. The back of the head appeared flattened. From one parietal eminence to the other extended a large hæmatoma, at the extremities of which were two minute punctures. On pressing this swelling, clots mixed with brain substance exuded from each. He was immediately anæsthetised, and an incision carried from one puncture to the other over the vertex. A double line of fracture was seen running from one parietal bone to the other, and extending on each side beyond the end of the incision. At the apex of the right parietal bone was a detached piece, which was depressed, and had penetrated the brain. From both extremities of the fracture brain matter exuded. A trephine was used, and the depressed piece was elevated. Two or three other pieces of bone which were detached were lifted out, and a stream of warm boracic lotion was forcibly injected, and altogether about a drachm and a half of brain tissue was washed out. The pieces of bone were kept in warm boracic lotion, were replaced as nearly as possible in their natural positions, and the pericranium brought over them and united with catgut sutures. A small drainage-tube was inserted at the right extremity of the wound. Except that a considerable amount of swelling of the forehead took place from extravasated blood, the child had no bad symptoms, and the greater part of the wound was healed on the ninth day. Granulations covered the two extremities of the wound, and except for an exanthematous rash on the fifteenth day, the boy had no bad symptoms. One minute crumb of bone came away from the wound over the left parietal bone. The accident happened a year ago, and the boy had had no headache, no fits, and the scars showed no depression nor any pulsation.

Mr. MORGAN showed a second case, that of a boy aged seven, who was knocked over by a hansom cab. He was conscious when admitted. Blood and brain substance were found on his collar. There was a scalp wound with jagged edges about three inches long over the right parietal bone, not exposing the bone. On the left side was an irregular wound reaching from behind the ear backwards towards the occipital protuberance, just above the situation of the superior curved line. As this exposed a fracture, an incision was made at right angles to the wound and running obliquely upwards towards the lambdoid suture. It was then seen that the squamo-parietal suture was separated, and a fracture was seen running across the upper part of the parietal bone from the lambdoid suture behind to the coronal in front. A large area of the parietal bone was depressed, and from the interval at the squamo-parietal suture brain substance and blood were oozing. The depression not being great, no attempt was made to elevate, but the parts were syringed with a forcible injection of boracic acid lotion, the pericranium adjusted, and the scalp wound united. The amount of brain substance lost was considerable, but could not be estimated. Every precaution was taken to render the wounds aseptic, but owing to the amount of dirt which had been ground in, that on the right side suppurated. The other healed directly, but about a month after leaving the hospital a small superficial abscess formed in the neighbourhood of the wound, which healed rapidly after being incised. The boy had remained perfectly well, and had had no fits.—Mr. SHEILD asked if, in a similar accident to an adult, Mr. Morgan would replace the bone.—The PRESIDENT inquired if any twitchings or convulsions had been observed in either case.—Mr. MORGAN, in reply, said he would be inclined to try the same expedient in the case of an adult; certainly no harm would be likely to follow under aseptic conditions. There were no convulsions.

Dr. WALTER CARR showed a boy aged eight years suffering from an early stage of Bronchiectasis. He had been subject

Digitized by Google

to winter cough from infancy, and this had continued during the summer for the last year or two. The boy was now rather blue, and very short of breath on exertion. The cough was distinctly spasmodic in character, but not accompanied by sickness, and no fetor of breath or expectoration was observed. Physical examination gave no sign of emphysema, and there was no deficient resonance over the lungs, but very abundant moist gurgling and bubbling râles were heard over both bases, especially on the left side. The heart was normal and the general nutrition was fairly good.

Dr. WALTER CARR also showed the lungs from a case of Bronchiectasis in a child just three years of age. The child had had whooping-cough when a year old, but apparently got quite well; it had never been free from cough for about twelve months, and had gradually wasted. It was treated for three weeks in the Victoria Hospital for Children in June, 1891, as a case of phthisis, but the temperature was usually subnormal, and only once rose above 100° F. Since June she had been an out-patient under Dr. Carr; she had a markedly spasmodic and choking cough, unaccompanied by sickness; the breath and expectoration were very fetid. The physical signs were those of general bronchitis, with very deficient resonance at the right base and gurgling râles, varying in number from time to time. The child died suddenly on Jan. 19th, owing, it was found, to pneumothorax on the left side, but the most important changes were found in the right lung—the upper lobe was mostly in a state of grey hepatisation, whilst the middle and lower lobes, which were very adherent to the chest wall, sank in water, and consisted almost entirely of bronchial tubes greatly distended cylindrically, and surrounded by firm fibrous tissue. Dr. Carr said that the cases usually began either as a chronic bronchitis which ran on to bronchiectasis rather than to emphysema; or they were a sequel to pneumonia, and the cases in which the disease was localised strongly suggested this. Nearly all these cases were apt to be regarded at first as instances of phthisis; but the fact that a subnormal temperature was present would help to distinguish them. The physical signs were limited to one or both bases, and there was very little general wasting until the later stages. In nearly all there was an absence of fetid breadth and of fetid expectoration. The prominent symptoms were the spasmodic cough, dyspnœa, cyanosis, and gurgling râles at one or both bases.

Dr. WALLIS ORD also brought two cases of Bronchiectasis in children. The first was a girl aged nine, who had had measles and whooping-cough seven years ago. Four years ago there was dulness and tubular breathing at the base of one lung: the temperature, which was at first high, afterwards became subnormal, and remained so. At the present time there was dulness at the left base below the scapula, with amphoric breathing, coarse râles, and pectoriloquy.

The second case shown by Dr. W. ORD was that of a boy aged four, who had likewise suffered from measles and whooping-cough, which in 1889 were followed by an attack of acute bronchitis of obstinate character. Six months afterwards bronchiectasis was discovered, which was at first mistaken for phthisis. The temperature was subnormal, and the boy had put on flesh since the summer. He was, unfortunately, unable to obtain sputum in order to demonstrate the absence of bacilli.—The PRESIDENT remarked that the occurrence of these changes independently of emphysema was interesting, and had not been observed by himself. In cases of diffused general bronchiectasis it was usual to find emphysema. Clubbing of the fingers was also a common accompaniment. He presumed that in Dr. Ord's cases, which were unilateral, the cause was an inflammatory one.—Dr. COLET-LARKIN of Ramsgate inquired if there were any family history of bronchiectasis in these cases.—Mr. BERNARD PITTS said that the diagnosis of bronchiectasis from abscess was important, in view of the possibility of surgical interference in these cases. He recently saw a case with Dr. Lees in which there were signs of a large cavity in the left lung, the patient being emaciated, the expectoration offensive, and the temperature fluctuating. There was no antecedent history of bronchitis or of foreign body. He resected a rib, allowed a week to elapse for the lung to become adherent to the chest-wall, and then incised the lung. He was unable to hit a cavity, although he got a little pus. At the end of a week an acute pneumothorax developed, for which the pleura was opened and drained, but the patient died. At the necropsy a large bronchiectasis was found which it would have been impossible to drain effectually. The large amount and the offensiveness of the expectoration were marked features in the case.—Dr. PERCY KIDD, referring to diagnosis, said that, unless putrescence of sputum were present, the nature of the case usually remained doubtful, but that putrid sputum, with periodical large evacuations, were characteristic of the affection. In many cases where the tissues looked healthy to the naked eye, under the microscope there would be found a lesion in the walls of the bronchi, a diffuse peri-bronchitis—the peri-bronchitis fibrosa of the Germans. They usually had recurrent attacks of bronchitis, and broncho-pneumonia, if it developed, did not go on to complete absorption; there was thus a repeated fibrinous deposit about the bronchi, impairing the elasticity of the tubes and favouring the occurrence of bronchiectasis. Surgeons usually found it hard to hit the cavities, they did not drain well, and the patients generally succumbed a few weeks afterwards. Under these circumstances, if a definite vomica were found, it might be right to recommend incision; but it should be explained to the patient and friends that the chances of success were slight.—Dr. CARR, in reply, referred to Dr. Fagge's observations on the occurrence of bronchiectasis without emphysema. He said that neither of the children he had shown had clubbing of the fingers, and there was no family history of importance. The diagnosis from abscess was helped by the facts that in bronchiectasis the onset was usually slow and the temperature subnormal. It was important to diagnose before putrescence was present. In four cases which he had published in the *Practitioner* putrescence was present in none, though the diagnosis of bronchiectasis was confirmed in all at the necropsy.—Dr. W. ORD, in reply, said that the younger child which he showed had distinct clubbing of the fingers. In the girl's case the lesion was certainly secondary to a broncho-pneumonia; but in the boy, who had been carefully observed for a very long time, no such lesion was noticed.

Mr. BERNARD PITTS showed a case of Plastic Operation for Contracture following Burn. The patient, a girl aged eleven, was badly burnt on the left arm in December, 1890, by the upsetting of a paraffin lamp; the burn extended over the greater part of the arm and over the upper part of the forearm. She was admitted to St. Thomas's Hospital in September, 1891, with a tense band of scar-tissue, causing flexion of the forearm at rather less than a right angle, the scar-tissue extending over the whole circumference of the forearm; the only healthy skin was at the posterior surface of the upper arm and over the posterior aspect of the elbow-joint. The elbow could be extended to a right angle, and flexed about fifteen degrees, rotation being fairly free. A month later the band in front of the elbow was divided down to the muscle and vessels, and the denser part of the tissue dissected away, a very wide gap of five inches being thus made. It was found impossible to completely straighten the arm, even when the superficial fibres of the biceps and of the muscles arising from the external condyle had been divided. A large flap of skin was then raised from the posterior aspect of the upper arm, glided across the gap, and secured in position with sutures. A considerable raw surface was still, however, left both above and below the flap, in addition to the large wound made by raising the flap. These raw surfaces were carefully covered by a number of parings from the skin of the thigh and legs, taken after the method of Thiersch. The grafts were cut as thin as possible with the razor, leaving the deeper structures of the skin behind and only just causing slight punctiform bleeding. The grafts varied in size from a florin to a five-shilling-piece. All these thin grafts lived, but one thicker piece, taken from the thigh and consisting of nearly the whole thickness of the skin, died. The condition of the arm was now very satisfactory, there being free movement in all directions, except some limitation of complete extension. This limitation was no doubt due to the burn having extended to the superficial part of the muscles. He found Thiersch's grafts of great value both in covering the raw surfaces above and below the glided flap and also in covering the wound at the back of the arm. He had not trusted entirely to this method of skin grafting, because he was anxious to have a substantial flap of glided skin across the bend of the elbow, it being more supple and less likely to be irritated by movement.

Dr. ORMEROD exhibited a male, aged nineteen, a labourer, who was otherwise healthy, but who appeared to be the subject of Syringomyelia. He experienced a sensation of pins and needles in the right hand seven or eight years ago, followed by inability to close his hand properly. The right hand, and subsequently the left, had wasted gradually. At present

Digitized by Google

there was atrophy of all the intrinsic muscles of the hands, and a certain amount of wasting of the muscles of the forearms, especially upon the flexor aspect, and most markedly in the right limb. The upper arms were in fair condition; there was no fibrillar twitching and no reaction of degeneration, but there was reduction of electro-contractility, and, indeed, abolition of it in some muscles. There was a well-marked lateral curvature, with its convexity to the left in the dorsal region. The lower limbs were natural, and the sphincters were not affected. As to sensation in the upper limbs, he felt touches, though apparently not perfectly, in the right hand; he also felt pain, such as pinching and dry faradaism, but confused heat and cold. On the strength of the chronic muscular atrophy, the lateral curvature, and the peculiarity of sensation, the case was brought forward as being probably syringomyelia.—The PRESIDENT asked where the exhibitor placed the lesion, and if he associated the cord disease in any way with the curvature.—Dr. TAYLOR considered that there was little doubt but that the case was one of syringo-myelia. The curve might be due to unilateral weakening of the trunk muscles as a result of the cord-lesion. It was peculiar in having such a very long history, but he had seen another case which resembled it in this respect, and in which the diagnosis was confirmed post mortem. In a second case he had examined the symptoms were of but two years' duration, but it was accompanied by so great a weakness that the patient could not stand or feed himself.

Mr. BRUCE CLARKE sent a case of Multiple Exostosis in a man of thirty-six, and one of the osteomatous growths had developed into a sarcoma. All the exostoses stopped growing at the age of twenty-five, but the mass in the abdomen started growing four years and a half ago, and now filled the whole of the left side of the pelvis. The inguinal glands were enlarged, there was difficulty of defecation, and increased frequency of micturition; pain was also present along the course of the great sciatic and obturator nerves.

Mr. MARMADUKE SHEILD showed a case of Primary Chancre of the Cheek. The patient was a woman aged thirty-four, and a widow. Near the centre of the left cheek was a formidable-looking, dusky coloured swelling the size of a florin. The edges were sharply defined, and it was devoid of discharge or ulceration. The submaxillary glands were much enlarged, and the skin covered with a dusky syphilide. The patient was taking mercury energetically, and the chancre had already reduced in size, while the rash had faded. The case had come under his care fourteen days ago. There was no history of infection, and all that was known was that the "sore" had existed for about two months. Mr. Sheild especially referred to an almost exactly similar case, with an illustration, published by him in the *British Medical Journal* of Feb. 5th, 1887.—Mr. WAINEWRIGHT remarked on the peculiarity of the chancre, which had changed in character since it had been under treatment.—Dr. HERON thought that if the lesion were primary it was too early to see periosteal symptoms; it might possibly be a secondary manifestation, the primary sore being situated elsewhere.—Mr. JULER had seen a great many cases of chancre on the eyelids. He would not at first have looked upon the lesion as primary, as it was associated with so many other symptoms of advanced syphilis.—Mr. SHEILD, in reply, emphasised the fact that the case was one of bad syphilis which had been untreated for three months, and in such cases it was not at all unusual for so-called late manifestations to occur early. In a bad case he had seen gummata in the testis four months after infection. In the present instance there was marked amygdaloid submaxillary bubo, and the skin was covered with an early syphilitic roseola. It was probably produced by accidental inoculation of a previously existing abrasion.

CLINICAL SOCIETY OF LONDON.

Tracheal Tugging in Aneurysm of the Aorta.—After-treatment for Scissors-legged Deformity.—Aneurysmal Varix.—Hypertrophy of Left Lower Extremity.—Aphasia.—Congenital Deformity of both Legs.—Amputation for Gangrene after Ligature of Femoral Artery and Vein for Punctured Wound.—Suppurating Pulmonary Hydatid treated by Incision.

AN ordinary meeting of this Society was held on Jan. 22nd, the President, Sir Dyce Duckworth, being in the chair. An exhibition of clinical cases first took place.

Dr. FREDERIC TAYLOR showed a patient who had Tracheal Tugging in association with Aneurysm of the Arch of the Aorta. After referring to the paper on this subject published in THE LANCET by Dr. McDonald in March last, Dr. Taylor stated that the patient possessed many of the usual signs of aneurysm; there was huskiness of the voice, inequality of the pulses, and diminution of breath sounds at the left base. On taking the cricoid cartilage firmly between the finger and thumb and lifting it upwards, the communicated pulsation or "tugging" of the aneurysm was distinctly felt.

Mr. BERNARD PITTS showed a case to illustrate the After-treatment for Double Ankylosis of the Hip, or Scissors-legged Deformity. The boy was nine years of age, and came under his care a year ago. The left thigh was ankylosed in front of the right, and he could only shuffle along on his toes. The ankylosis was osseous, and was the result of inflammation following a fall four years previously. He had been treated by extension in the Leicester Infirmary. Mr. Pitts first made a section of the left femur below the trochanters, and fixed it in a straight position. He then took a wedge out of the neck of the right femur, but this procedure was followed by suppuration and necrosis, necessitating the excision of the head of the bone. Movement had since been kept up on the right side, and the boy for the last month had been able to walk.

Mr. FREDERICK PAGE of Newcastle showed a pitman who, five weeks ago, received a stab in the left side of the neck. Hæmorrhage was at first checked by pressure, then the wound was enlarged, and a vein which was divided was tied. The next day a swelling was found which extended from the thyroid cartilage to the sterno-clavicular joint, and there was a thrill which was characteristic of a communication between an artery and a vein. The exhibitor thought that the lesion was an aneurysmal varix between the carotid artery below its bifurcation and the internal jugular vein; he gave reasons for this opinion. The patient at present complained of a constant buzzing noise, and he could not express himself freely. Mr. Page referred to a case of aneurysmal varix in the popliteal space which occurred a few years ago, and in which, after twelve years, an aneurysm of the popliteal artery developed.

Dr. COUTTS and Mr. DUNN exhibited a girl with Hypertrophy of the Left Lower Extremity. The limb commenced to swell shortly after an attack of scarlet fever, and the hypertrophy now involved all the tissues. There was neither albuminuria nor chyluria, but Dr. Coutts thought he had found a worm in the blood larger than filaria sanguinis hominis. The femoral artery had been tied, and since then the limb had decreased in size.

Dr. HADDEN brought forward a woman, aged twenty-seven, affected with Aphasia. A year ago she was attacked by right hemiplegia, which was apparently of syphilitic origin. She could remember very few words, but her automatic utterances remained, such as the words of a few hymns and prayers. There was no heart disease.

Mr. OPENSHAW exhibited a child with Congenital Defects of the Upper and Lower Extremities. There was no family history of similar deformity. There were deep grooves round both legs, and both fingers and toes were undersized, and for the most part nailless. The left foot exhibited talipes equino-varus. There was no spina bifida.

Mr. MANSELL MOULLIN demonstrated a case of Fracture of the Lumbar Spine for which he had performed laminectomy. On Jan. 1st, 1891, the patient had fallen down a chalk pit, and was picked up unconscious with the lower limbs paralysed. The medical man who saw him extended the spine manually, which was followed by temporary improvement; still he could not move the left hip, and both limbs below the knee remained paralysed. Nine weeks after the accident he removed the second and third lumbar spines, with the corresponding laminæ, and as the second lumbar vertebra appeared to be twisted he removed its right lower articular process. He was unable at the operation to determine the nature of the injury. Two days afterwards sensation on the left side began to improve, and he had now completely recovered power except in the left tibialis anticus and the extensors of the toes. These muscles, however, were the only ones which had lost their reaction to faradaism before the operation; but at the present time (twelve months after the operation) they commenced to show signs of returning power.

Mr. LEONARD BIDWELL showed a woman forty-seven years of age who five years ago noticed Pigmentation at the end of the Thumb, and six months ago a Melanotic Tumour formed.

Digitized by Google

At the end of last September he removed the tumour, together with the surrounding skin. Before the wound cicatrised pigmentation commenced round the scar, which had since increased in extent; but there was no recurrence of the tumour, an enlarged axillary gland being apparently accounted for by a sore on the back of the hand. There was no history of a mole existing at the site of the growth.

Mr. HERBERT ALLINGHAM read a paper on a case of Punctured Wound of the Thigh, in which the femoral artery and vein were divided. Gangrene of the leg followed ligature of the proximal and distal ends, and the limb was finally amputated through the knee joint. Frank S——, aged twenty-eight, was admitted into the Great Northern Hospital on Nov. 30th, 1889. While cutting some bacon with a long, sharp butcher's knife his hand slipped, and the knife penetrated the inner part of the right thigh just at the apex of Scarpa's triangle. A considerable deal of blood shot out. He at once applied pressure, and was brought to the hospital, where, after a tourniquet was applied, it was found there was a small wound about an inch long, from which, on loosening the tourniquet, blood spurted. The surrounding tissues were infiltrated with blood, and there was no pulsation in them. The whole of the limb was tense and very swollen, the foot was quite cold and pale, and there was no pulsation in any of the vessels of the leg. The patient's general condition was bad, he was very blanched, complained of thirst, swimming in the head, and was extremely restless. Esmarch's bandage was applied and the divided vessels cut down upon. On exposing the sartorius it was seen that that muscle had been penetrated, so it was cut across and the ends turned upwards and downwards. A large blood clot was then exposed and turned out, and at the bottom of the cavity was seen the femoral artery and vein completely divided just as they entered Hunter's canal. Both ends were secured. The wound was then sewn up, having been previously well irrigated. The leg and thigh were enveloped in cotton wool, and kept warm with hot bottles. The next day the leg appeared warm, but on Dec. 2nd, two days after the operation, the foot began to have a waxy appearance. The calf became much swollen and painful, and on Dec. 3rd the foot had become gangrenous, of the dry variety, and this increased and spread very slowly up the leg to about the middle of the calf. The leg remained in this condition until Dec. 23rd—when the temperature rose to 105°, the gangrene becoming moist, and with that state of things he amputated at once through the knee-joint by Stephen Smith's method, and the next day the temperature returned to normal. When amputated it was seen that both the popliteal artery and vein were plugged, and the cutaneous vessels bled rather freely. The wound was a long time in healing, as the edges of the skin sloughed. The interest of this case lay in the following facts:—The gangrene when once pronounced did not extend for three weeks. Amputation was done through the knee-joint. His reason for delaying to remove the dry gangrenous leg was because, since the constitutional symptoms were favourable, it was better to wait in order that the collateral circulation might become well established. If he had amputated early he thought the incision would have had to be made through the wound in the thigh, where the femoral vessels were ligatured, as that wound was not healed, and therefore there was still a fear of secondary hæmorrhage.—Mr. HARRISON CRIPPS said that two questions were raised for discussion: the primary treatment of the case and the right time to perform amputation after gangrene appeared. If there were doubts what vessel was wounded, he held it right to trust at first to graduated pressure properly applied, the limb being bandaged from below upwards, an outside splint put on, and a roller firmly applied above and below the wounded spot. But in the case related the evidence was so clear that the femoral was divided that the right practice was at once to cut down and tie the ends. When gangrene occurred the practice should be the same whether it were due to wound, ligature, or embolism of the artery. The portion of limb which died was usually the foot with the lower half of the leg, the thigh generally not being affected. The gangrene usually caused but little constitutional disturbance, and in that case the line of demarcation should be waited for; it was usually about four inches below the knee, and amputation should be performed immediately above it. If the patient were old and feeble nature might be allowed to effect separation down to the bone.

Dr. W. M. ORD and Mr. H. B. ROBINSON contributed notes of a case of Suppurating Hydatid of the Lung, treated by incision of the lung and removal of the hydatid. The patient, a youth aged eighteen, a telegraph messenger, was admitted to St. Thomas's Hospital on Oct. 25th, 1890. He had had "pleurisy" in the right side four months before admission, was in bed for two weeks, and then "recovered completely." He had had a cough for five weeks before admission, and after this had lasted two weeks he was seized with a pain in the right side, and brought up a quantity, estimated by him as half a pailful, of an opaque yellowish-white fluid. From that time he was confined to his bed, could only lie on his right side, and suffered from considerable dyspnœa. He had had profuse expectoration, and latterly troublesome diarrhœa. On admission the patient was pale and sallow, with a hectic flush and a look of anxiety. His breathing was rapid, short, and painful, and his breath fetid. The temperature was 101°; pulse 120; respiration was almost entirely diaphragmatic, and was 54 to the minute; there was dulness over the lower fourth of the right lung behind and impaired resonance as high as the fourth rib in front; vocal fremitus was slightly increased over the dull area, and loud bubbling crepitations were heard (a few hours after admission these disappeared, and were replaced by cavernous breathing, the patient having coughed up in the meantime more than a pint of frothy and offensive muco-pus); there were bronchophony and whispering pectoriloquy over the dull area; there was tubular breathing, with increased vocal fremitus, over the base of the left lung posteriorly. Heart and abdominal organs normal. The diarrhœa continued after admission. Stools liquid, brownish-yellow, and offensive; urine, sp. gr. 1030, no albumen, sugar, indican, or blood. Some hours after admission an exploratory puncture was made, and about one ounce of thin sanious blood was obtained, with numerous flakes of membrane; no hooklets were found; the sputum contained neither hooklets nor tubercle bacilli. The symptoms pointing to a large cavity actively secreting pus, Mr. Robinson, on the third day after admission, proceeded to operate. No general anæsthetic was used, but the ether spray was employed for the skin incision, which was made from the angle of the seventh rib to the inferior angle of the scapula, the periosteum of the rib was detached, and one inch and a half was resected. On careful section in the space thus left a cavity was reached about a quarter of an inch from the rib. No pleural cavity was found, and on cutting into the lung there was no hæmorrhage. About half a pint of stinking pus, with gas, escaped from the wound, followed by a very large and collapsed hydatid cyst. Two drainage-tubes were introduced, but owing to the patient's condition the cavity was not washed out. Soon after the operation the patient had a rigor, and the temperature rose to 102·4°, but sank to normal four hours afterwards. The wound was dressed in the evening, with the escape of a large quantity of pus. On the following day the cough was not so troublesome and the expectorations hardly offensive. The cavity was washed out with three pints of weak Condy's fluid. This was repeated on the following two days, at intervals of twelve hours, and the discharge became less profuse and less offensive. The diarrhœa continued very bad, and the patient gradually became exhausted, and sank on Nov. 10th, thirteen days after the operation.—Post-mortem examination: A large cavity occupied almost the whole of the lower lobe of the right lung, and about the artificial opening only a very thin layer of lung could be seen beneath the greatly thickened pleura. The cavity had a smooth wall, and, though containing some shreds of exudation, was practically empty. The surrounding lung was the seat of chronic interstitial pneumonia. Between the parietal and visceral layers of the pleura round the upper lobe was an empyema, which had no connexion with the hydatid cavity. The upper lobe was compressed, and the seat of acute broncho-pneumonia. The lower lobe of the left lung was semi-solidified by collapse and broncho-pneumonic foci. There was acute pericarditis, but the cardiac valves and muscle were normal. The liver contained two hydatid cysts. The other organs were healthy, and no other cysts were found. It was evident at the time of admission that he had a large abscess of the right lung partially discharging through the bronchial tubes. The enormous amount of discharge occurring suddenly five weeks before suggested the existence either of a suppurating hydatid or of empyema bursting through the lung. The latter supposition was not favoured by physical signs. The operation would have been performed earlier but for the necessity of communi-

Digitized by Google

cating with the boy's parents. As an operation for pulmonary abscess it proved successful, but from the long previous duration of the case pyæmic infection had occurred.—Mr. C. MANSELL MOULLIN gave details of a case of hydatid cysts of the liver, which ruptured into the peritoneal cavity, and in which abdominal section was performed. The patient was a thin anæmic youth, aged nineteen. The tumour was first perceived eight years ago. In September, 1889, something gave way in the abdomen; the swelling disappeared, and an eruption of urticaria, with slight shock, followed. Ascites set in afterwards, and the patient was admitted into the London Hospital under Dr. Stephen Mackenzie. The abdomen was aspirated on three occasions, fifteen to twenty pints of dark greenish-brown fluid being evacuated each time. Hooklets were found in the last. Abdominal section was performed on Dec. 28th, an immense quantity of fluid draining away. Recovery was very much delayed by the slowness with which the cyst wall separated and the difficulty of extracting the sodden fragments. In about three weeks bile ceased to make its appearance, but the patient did not rally. A few days later a second much larger cyst with thicker walls burst into the suppurating cavity, the shock on this occasion nearly proving fatal. Then the cavity slowly contracted, and the patient was discharged with the wound healed in April. Attention was directed to the very different estimates of the mortality attendant on rupture of the hydatid cysts into the peritoneal cavity and the great difference to the severity of the symptoms, especially the degree of shock. It was pointed out that the symptoms of poisoning that usually followed could only result from some constituent of the fluid itself, possibly a ptomaine, the presence of which in living active cysts had been shown by Langenbuch and confirmed by Brieger and others. This would also serve to explain the results obtained experimentally by Roy and Humphry. On this supposition the subsequent onset of peritonitis and its severity must be regarded as dependent chiefly upon the nature of the débris that entered the peritoneal cavity at the same time.—The PRESIDENT asked the experience of surgeons as to whether these cavities should be washed out. His own feeling was that they should not be so treated.—Mr. HOWARD MARSH said that the difficulties were very great when one attempted to do anything active surgically to the lung itself. The hæmorrhage on incision into its substance was profuse, and there was great difficulty in getting sufficient room, even if ribs were freely removed. It was a difficulty, again, to leave the wound in an aseptic condition because of the usual free communication with bronchi. He referred to a case in which a patient had apparently a simple empyema, but the sinus would not close. Portions of ribs were removed, and there was extremely severe hæmorrhage. The sinus still remained open, and a quantity of blood had since escaped both from the sinus and by way of the bronchi, though he had no clue as to its cause. He thought that hydatid cavities should not be washed out. A little time ago he saw a lady, in consultation with Dr. Douglas Powell, with a chest complaint. It was thought to be empyema and a portion of rib was resected, when there gushed out a large quantity of hydatid material. It must have been hepatic in origin, for afterwards there was a free discharge of bile; the patient ultimately did well. He once nearly destroyed a patient by washing out with weak iodine a chest cavity which communicated with a bronchus.—Mr. ROBINSON, while agreeing that as a rule chest cavities should not be washed out, pointed out that in the case under discussion the cavity was large, the pus was malodorous, and the patient was suffering from septic poisoning. The injection of a small quantity of weak Condy's fluid had no bad effect whatever.—Dr. ORD, in reply, while agreeing that a cavity containing living hydatids might be opened and left, yet when they were suppurating he saw nothing to distinguish them from any other abscess, and held that it was proper treatment to wash them out.

MIDLAND MEDICAL SOCIETY.

WEDNESDAY, DEC. 9TH, 1891.

Mr. BENNETT MAY, F.R.C.S., President, in the chair.

Bulbar Paralysis, with Bilateral Paralysis of the Abductors of the Vocal Cords; Death after Tracheotomy.—Dr. SUCKLING read notes of the case of a man aged forty-three, a commercial agent, who was admitted into the Queen's Hospital under his care on account of attacks of urgent dyspnœa. He had been ailing for three or four years, and had gradually become worse. His speech was slurred and thick. The lower lip hung down flabbily, and he had to press it against his gums when eating. There was distinct paresis in the lower part of the face on the left side. He suffered also from dysphagia, especially for liquids. The soft palate and uvula were relaxed, but not quite paralysed. He could protrude the tongue, but its movements were feeble. Phonation was feeble. He had no power of expectorating, and this gave him much discomfort. There was paresis and wasting of the left deltoid, and wasting of the left supra- and infra-spinati. The thenar eminence on both sides was flattened. The vocal cords were adducted on inspiration, and were drawn closely together, occasioning stridor; on expiration they were slightly separated, the edges vibrating. Dr. Suckling did not consider it safe for the patient to leave the hospital until tracheotomy had been performed, and the patient himself was very anxious to have the operation done. He was in a very feeble state, being obliged to sit up in bed to breathe, and his breath sounds over both lungs were very feeble. A few hours after the operation was performed, no anæsthetic being used, the patient became suddenly worse and was cyanosed. The breathing became very slow and shallow, and soon ceased. There were no history of syphilis, the knee-jerks were normal, and there were no signs of locomotor ataxia. A microscopic examination of the medulla had not yet been made. The occurrence of paralysis of the abductors of the glottis in bulbar paralysis was rare. The man had been a drinker, but had never worked in lead.

Sarcoma of Radius.—Mr. HEATON showed this specimen. The clinical history was very meagre. Had noticed swelling of forearm for three months. Swelling was painless, but slightly tender on pressure, and had lately become more tender. Three days before admission it suddenly increased in size. Typhoid fever six months before; no history of tumour. He had fairly well-defined swelling in upper two-thirds of right forearm, chiefly over dorsal aspect of radius. Swelling firm and elastic, softer in places, tender, attached to radius; no pain in swelling at night, nor rise of temperature. Diagnosis lay between chronic ostitis, periostitis, or some form of new growth. The attacks of pain, rapid history, also of raised lump and history of sudden increase in size without any evidence of inflammation, all pointed to new growth. Grooved needle drew off a little blood. An incision made into tumour showed bone enlarged, and encountered a soft, vascular, marrow-like tissue. Amputation refused, but consent afterwards given; performed. Boy made good recovery; seen a few weeks ago in good health. The specimen was a well-defined and encapsuled sarcoma of shaft of radius. Bone thickened by deposit of new bone from periosteum. Growth seemed to have started in the medulla, but, instead of expanding the bone, to have perforated it and enveloped it as a periosteal sarcoma would. Tumour, very vascular when fresh, had shrunk and become pale in alcohol. Microscopically, a myeloid sarcoma, with numerous well defined multi-nucleated giant cells. The case is interesting on account of the extreme rarity in which a myeloid sarcoma grows from the shaft; nearly always at one articular end, and then expands the bone around it.

Disease of Testicles.—Mr. BARLING showed a patient, aged thirty-one, with acute tubercular disease of both testicles. The disease was attributed by the patient to an injury three months ago, but the history of this is uncertain. When first seen each epididymis was a good deal enlarged, irregular, and very tender; a little fluid existed in each tunica vaginalis, and the cord was rather thickened and the skin of the scrotum red. There was no appearance or history of urethritis; no evidence or history of syphilis. The temperature at night varied from 101° to 103°, and in the morning was about 99°. No definite evidence of any other tubercular lesion could be discovered in the body. At the present time the disease had extended to the body of the testicles on each side, and the enlargement was steadily increasing. The left testicle was the size of a small fist, and both were very tender. The patient was advised to have double castration performed (after exploratory incision) for two reasons—viz., the disorganised condition of the testicles rendering them functionless, and the danger of general infection and of extension to the base of the bladder. Operation was declined.

Digitized by Google

Retroversion of the Gravid Uterus.—Dr. PURSLOW read notes of a case of retroversion of the gravid uterus. The patient, who had had four children and no miscarriages, was admitted at 6 P.M. on Nov. 14th, complaining that she had been unable to pass urine from noon on the previous day; no other symptoms. Last menstruated on Aug. 1st. On examination the bladder was distended, reaching to umbilicus, and there was a well-marked retroversion of uterus, the os being high up behind the pubes, and the fundus forming a large doughy swelling in posterior part of the pelvis. After withdrawing urine an attempt was made to replace fundus by pressure of fingers in vagina and then in rectum, but this did not succeed. The patient was then placed in genu-pectoral position, and the uterus righted itself, and there was no further trouble. Dr. Purslow urged the importance of trying replacement in genu-pectoral position before proceeding to give an anæsthetic.

Biliary Calculus.—Mr. CHRISTOPHER MARTIN showed a biliary calculus removed ten days previously by Mr. Lawson Tait by the operation of cholecystotomy. The patient was a middle-aged woman who had suffered from repeated attacks of biliary colic during the preceding three months. Each attack was followed by violent bilious vomiting, but never by jaundice. She had never found gall-stones in the fæces, nor had the stools been pale in colour. On examination the gall-bladder was found to be greatly enlarged, reaching to two inches below the umbilicus. It formed a smooth fluctuating mobile swelling the shape of a soda-water bottle. At the operation it was found to be distended with a clear, colourless mucous fluid, in which not a trace of bile could be discovered. There was but one stone, and this was impacted in the neck of the gall-bladder. It was about the size and shape of a nutmeg, and remarkably tuberculated on the surface. The patient was making an excellent recovery.

Mr. ROSS JORDAN read a paper on the Lunacy Act of 1890, and the certification of lunatics.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

Mr. A. R. ANDERSON, F.R.C.S., President, in the chair.

THE meeting on Jan. 6th was a Clinical and Pathological evening.

Mr. TRESIDDER showed a boy on whom he had removed a piece of the cartilage of the ear for the remedy of out-standing ears.

Mr. GERATY described the case of a man aged sixty who suffered from Multiple Sarcomatous Tumours. When first seen there was only one nodule on the forearm. This was excised, and soon afterwards superficial nodules appeared on the trunk and face. Many of these had a purpuric zone round them. Some small nodules were observed to diminish in size and ultimately disappeared, while fresh ones continued to appear. The patient suffered no pain, but became weak and anæmic-looking. He died a year after the removal of the original tumour.—Dr. W. H. RANSOM followed with remarks on the spontaneous recession of Sarcomata. He remarked on the rarity of this occurrence, and mentioned instances of it in medical literature and coming within his own knowledge. He also alluded to cures of sarcoma which have been reported under the use of arsenic, the iodides, and mercury. There were three varieties of nodule in Mr. Geraty's case: (1) A patch of discolouration not raised above the surface in which blood-corpuscles were found, but no sarcoma cells, although they were probably present; (2) extravasation of blood into a sarcoma nodule provided with limiting capsule; (3) infiltrating growths without capsule. He considered the essential cause of recession of the growths was hæmorrhage, the effect of which was to destroy the vitality of the cells and render the mass capable of absorption.—Dr. HANDFORD found arsenic useless in lympho-sarcoma infiltrating the neck.—The President and Dr. Boobbyer also spoke.

The PRESIDENT reported two cases in which he had successfully removed large Tumours from the gluteal region. Both occurred in women. In one the growth proved microscopically to be a myxo-fibroma; it was about the size and shape of a Rugby football. In the second case, a small lump which had existed for many years began suddenly to enlarge, and at the time of operation had attained the size of a child's head, on weighing removal 5 lb. A microscopic section, prepared by Dr. W. H. Ransom, showed the tumour to be an atheromatous cyst undergoing sarcomatous degeneration. Islets of sebaceous cells were to be seen amongst the sarcomatous tissue. He also referred to (1) a case of pure adenoma of the breast, a microscopic section of which was shown, and commented on the rarity of this growth; (2) a case of carcinoma uteri which he had successfully removed by vaginal hysterectomy; and (3) a case of melano-sarcoma of the ciliary region with cataract.

Mr. TRESIDDER related the case of a man, aged seventy-one, who had been ill eleven days, and was admitted into the hospital with symptoms of obstruction. Laparotomy was done, and the man died. A specimen was shown of the cæcum surrounded by an abscess cavity in which lying free were the appendix and a foreign body.

Mr. TRESIDDER also showed specimens of Gastro-enterostomy. The operation was unsuccessful, and was performed on a patient already much weakened by cancer of the pylorus of seven months' duration. Duodenal ulcer had been diagnosed during life, and Mr. Tresidder discussed the difference between gastric and duodenal ulcer. Death occurred from hæmorrhage. The size of the ulcer was an inch and a half by half an inch.

Specimens.—Mr. ANDERSON: Tumour of Buttock; Uterus removed for Carcinoma; Sarcoma of Ciliary Region; Adenoma of Breast.—Dr. W. H. RANSOM: Sarcomatous Testicle; Microscopical Sections of Sarcoma, Myxo-fibroma, Spindle-celled Sarcoma, and Adenoma of Breast.—Mr. CLEMONS (for Mr. Anderson): Sarcoma of Ciliary Region.—Dr. CATTLE: "Fuchsine Bodies" in Carcinoma, which were considered due to the deep staining of globules of degenerated protoplasm; Sections showing development of Mammary Carcinoma from the Epithelium lining the Alveoli.

Reviews and Notices of Books.

An Introduction to Human Physiology. By AUGUSTUS D. WALLER, M.D., Lecturer on Physiology at St. Mary's Hospital Medical School. London: Longmans, Green, and Co. 1891.

IN this work, which we gladly welcome from so excellent a teacher, Dr. Waller presents what in his judgment are the chief points in physiology that should be understood by the medical student. The arrangement adopted by Dr. Waller is to consider in the first place the phenomena of nutrition, including the blood circulation, respiration, digestion, secretion, the balance of the economy and animal heat; and in the second part the phenomena of excitation, including the nervo-muscular apparatus and senses. Each chapter is preceded by a syllabus of the subject, which may be of use not only to the student but to the teacher, by showing the order in which the subjects treated of are discussed. The first one, under the head of Circulation, is particularly full, and gives the page on which each point is treated. In this chapter we notice an instructive woodcut giving the duration of systole and diastole, with different pulse frequencies, showing that the systole shortens by about two one-hundredths of a second for each increase of ten beats per minute, and that the diastole shortens by about ten one-hundredths of a second. The nature, mode of determining and variations of blood-pressure are well and clearly given, but call for no special notice. The author estimates the quantity of blood discharged from the heart into the arteries at each systole at four ounces.

The chapter on Respiration contains a drawing of an ingenious and handy little apparatus for determining the quantity of oxygen and of carbonic acid gas in expired air. In regard to ventilation, he observes, the air of a room in which respiratory CO_2 does not exceed 2 per 10,000 is fresh, when the respiratory CO_2 is between 2 and 4 per 10,000 the room begins to feel close, between 4 and 6 per 10,000 it is

Digitized by Google

decidedly close, between 8 and 10 the air is foul, and beyond this limit intolerable for any length of time; 2 per 10,000, or 1 per 5000, is thus the limit of expired CO_2, admissible in perfect ventilation, and should never be exceeded. The term "respiratory CO_2" does not seem to us to be a happy one, and the student is apt to forget that four parts per 10,000 have to be added to each of the above numbers to represent the quantity present in ordinary air. The mode of calculating the quantity of fresh air required for good ventilation is well put: "Remembering that every 1 cc. of expired CO_2 is to be diluted by at least 5000 cc. of fresh air, an adult expiring fifteen times per minute 500 cc. of air containing 20 cc. of CO_2 exhales in one hour 18 litres of CO_2, which to be diluted 5000 times requires 90,000 litres of air—i.e., the fresh air required during the hour is 90,000 litres, or 3000 cubic feet." This is the normal amount of fresh air per head per hour which should be provided for in the ventilation of dwellings intended to be "healthy." The author points out that the waxing and waning of the respiratory rhythm characteristic of the Cheyne-Stokes respiration stands in some relation to the Traube-Hering rhythm in the vaso-motor system, for both rhythms are originated by medullary centres, and are of about the same frequency—viz., 1 to 3 per minute, the association being sometimes most definite and exact; in the rabbit, for example, after hæmorrhage phases of increasing and diminishing amplitude of respiration, coinciding with rise and fall of blood pressure; they are instances, among many others, of the common tendency towards pulsatile or rhythmic action manifested by all living matter. A very good section is devoted to the respiration of muscle as illustrating internal respiration, and much information not to be found in other works on physiology is given in regard to the formation of CO_2 by muscle, showing that in contraction, after death and at 40°, muscle yields CO_2 and becomes acid; at 70°, although it becomes rigid, it does not yield CO_2 or become acid, whilst at 100° it yields CO_2 and becomes acid.

Incidental remarks often suggest that Dr. Waller is a practical physiologist, and has made the experiments he describes. For example, after remarking that after severance of the head of an animal a little salivary secretion can be induced by stimulating the chorda tympani, he adds: "The observation is less convincing in the fact than in the account of the fact—only a drop or two of saliva can thus be obtained,—and room is left to imagine that this minute quantity is squeezed out rather than secreted." Intestinal juice he regards as having only a very slight digestive action on food stuffs, its most characteristic effect being the conversion of cane sugar or saccharose into invert sugar or lævulose and dextrose, by virtue of the ferment named "invertin." Glycogen he regards as a temporary carbo-hydrate reserve. Absorbed sugar, he says, enters the blood, is to a great extent stored as glycogen in the liver, is consumed by living muscle, and is discharged as CO_2, and as H_2O.

The chapter on Digestion is short, though no fact of cardinal importance is omitted. The time occupied for a complete act of deglutition is given at from 17 to 19·5 seconds for man. This period appears to be extraordinarily protracted. Surely it does not occupy more than a quarter of a minute for a bolus of food to reach the stomach. In regard to the vexed question of the termination of nerve fibres in the cells of salivary glands, Dr. Waller only remarks that all attempts at the demonstration of the junction have been unconvincing. He gives a very full and good account of the alterations observed in the cells of serous and mucous glands respectively in the resting and active state.

In the chapters on Muscle and Nerve a brief histological introduction is given, which is preceded by a very useful section on electro-physiological instruments. The meaning of the terms ordinarily employed in research, such as ampère, ohm, volt, rheostat, rheocord, Wheatstone's bridge, commutator, galvanometer, and others, are explained more clearly than we have elsewhere seen, and are accompanied with rough diagrammatic but very intelligible figures.

Under the head of the Spinal Cord and Bulb, Dr. Waller gives a short description of the structure of the cord, with a cut showing the arrangement of the columns in transverse section. Another woodcut gives an ideal longitudinal section, and showing that Clarke's column and the intermedio-lateral tract are rather to be regarded as islands of grey substance than as columns, and showing also the relations of these islands with the cervical sympathetic and cardiac accelerator nerves and with the splanchnic nerves. In regard to the *quæstio vexata* of the course of the motor and sensory fibres, after pointing out the inconsistency of the generally accepted doctrine that the motor fibres cross at the bulb and the sensory fibres in the cord, he remarks, "We seem, in fact, to be approaching the conclusion that sensory as well as motor channels have their major decussation in the bulb, their minor decussation in the cord; in which case we must admit that sensory impulses from each side of the body can pass up both sides of the cord, but most on the same side." He takes exception to the expression "centre for" such-and-such an action, considering that it implies a mapping out of the bulb and cord into departments far more definite and artificial than in reality exists, and is an illegitimate dictation of final causes. It appears, however, to be only a convenient mode of saying that a certain anatomical region from which nerves supplying one or a number of muscles take origin, and most teachers probably explain this in speaking of such centres.

The difficult subject of Cortical Localisation is sensibly and temperately discussed. The balance of evidence, the author thinks, is in favour of localisation, whilst the counter-evidence has shown that localisation is not sharply defined but blurred; and he suggests as an analogy that the various activities of the brain are not generally distributed as in a country without towns, where all kinds of industry go on in every hut, nor are the different activities absolutely restricted to certain spots, as if in walled towns. "The brain cortex is not comparable with either of these extreme cases; its territory must be recognised as possessing towns with special industries, but towns with straggling and overlapping suburbs, and industries which are indeed predominant each in a given centre, but not exclusive of all other industries in that centre, nor excluded from other centres in which other industries predominate." This appears to express very happily the conditions existing in the brain cortex.

The limits of the space at his command and the belief that the subject is beyond physiological bounds have led him to deal very summarily with the development of the embryo. Only an outline of the earliest stages is given.

We have quoted enough to show that Dr. Waller has written a very serviceable manual for the student, and one which may be regarded as well up to date. The author has had large experience in teaching, is at home in the laboratory, familiar with the use of instruments, and very competent to estimate the value of physiological experiments and doctrines, and their bearing on clinical medicine.

OUR LIBRARY TABLE.

Journal of the Marine Biological Association of the United Kingdom. Vol. ii., No. 2, Nov. 1891. London: Dulau and Co.—From this journal we gather that Professor E. Ray Lankester has been elected President in place of Professor Huxley, retired. The receipts, including a

Digitized by Google

small charge for admission, have been £1925 5*s*. The condition of the tanks is annually improving, and a self-sown fauna of hydroids, ascidians, and chætopods is slowly springing up. Eleven gentlemen have occupied tables in the laboratory. Attempts, not hitherto successful on account of the difficulty of obtaining a suitable situation at a reasonable cost, have been made to obtain ponds for the artificial rearing of soles and of lobsters. So many anchovies were brought to the laboratory last year of large size that an anchovy drift-net has been purchased, and it is hoped that a regular fishery may be established. The papers contained in this part are: 1. The Egg and Larva of Callionymus Lyra, by J. T. Cunningham, and, by the same writer, Experiments on the Production of Artificial Bait; also the Rate of Growth of some Sea Fishes and their Distribution at different Ages; the Reproduction and Growth of the Pilchard and the Development of Palinurus vulgaris or Sea Cray Fish. 2. Walter Garstang on some Ascidians from the Isle of Wight. 3. Physical Investigations, by H. N. Dickson.

La Neurasthénie. Par le Dr. FERDINAND LEVILLAIN. Paris: A. Maloine. 1891.—Dr. Levillain's work is sandwiched between the inevitable preface by Charcot and a paper by another writer. The work itself is a very full one, and the subject is discussed in a manner which shows that the author has a thorough grasp of it. He begins at the very beginning by giving a history not only of the thing itself, but also of its name, and, after a rapid discussion of its nature and etiology, the bulk of the book is devoted to a full account of the symptoms and objective signs of the malady. Prognosis and diagnosis are also discussed, the subject of treatment in its various forms is entered into with the necessary amount of detail, and the book is rendered very complete by an appendix, in which the medico-legal aspects of neurasthenia are discussed. A very complete bibliography, which is sure to be useful, is also added.

La Suisse: Balnéaire et Climatérique. Par Dr. EUGÈNE DE LA HARPE. Zurich: César Schmidt.—Dr. de la Harpe's little book treats of the various Swiss health resorts in an exhaustive and scientific manner, and contains many valuable hints as to the class of patients for which each health resort is suitable. In addition to the already well-known "cures," Dr. de la Harpe brings into notice some places as yet little known. Among them Arosa may be mentioned, and Weissenbourg. Arosa may be reached from Coire and Langivies; from the latter place the journey is short and easy. High mountains surround it on three sides, and it stands at an altitude of 1900 metres, the north-west side alone being open. The scenery is grand and of a severe character, with forests of pines on the southern side, and there are several small lakes. The climate is bracing, subject to rather rapid changes of temperature, but as a rule the air is very dry. The climate in winter is as yet imperfectly known, since Arosa has only been used as a summer resort. The great attractions of Arosa are the purity of the air and the absence of dust. Dr. de la Harpe recommends it for patients in the early stages of phthisis. Weissenbourg, which is three hours and a half from Thun, is noted for its sulphuretted lime and magnesia waters. The baths of Weissenbourg are situated in a narrow valley watered by the Bunschenbach. The sides of the mountains which enclose the valley are covered with pines. The air is pure and free from dust, and the smell of the pines very pleasant. The chief characteristic of the climate is the dampness of the air, due to the large forests round the valley; it is also variable. Invalids are subjected to a strict regimen with regard to diet and alcohol. The best results are said to be obtained in tuberculosis of the larynx and in the sequelæ of inflammatory diseases of the lungs.

The Johns Hopkins University Circular, Vol. XI., No. 93, is devoted to the full text of the addresses delivered at a meeting held in the Physical Laboratory of the University on Oct. 13th to celebrate the seventieth birthday of Professor Virchow. The addresses are remarkable for the genial and lofty spirit which animates them, and the warm recognition they give to the life-long labours of the illustrious pathologist. Professor William Osler speaks of "Virchow, the man and the student"; Professor William Welch of "Virchow, the pathologist"; and more general tributes are contained in the addresses of Professor Samuel C. Chew, of the University of Maryland; of Professor A. Friedenwald, of the College of Physicians and Surgeons, Baltimore; and Professor A. Jacobi, of the College of Physicians and Surgeons, New York City. The celebration was one which did honour to those who shared in it, whilst it showed the gratitude that the followers of medical science in the New World bear to the inspiring work of their master, Virchow.

Analytical Records.

VARIOUS SOAPS.

(PRICE'S PATENT CANDLE COMPANY, LIMITED, LONDON AND LIVERPOOL.)

SOAPS are amongst the excellent productions of this well-known firm, no less than six kinds having been submitted to us for examination. The statements made in reference to each and all are, according to our analyses, quite accurate. Thus Regina is a dehydrated soap, milled and free from excess of alkali; Bonne Mère Nursery Soap is admirably fitted for the purpose implied by its name; Glycerine Cream is desiccated, milled, and extra perfumed; and Bath Soap is a cheap but none the less good variety freed from all irritant matter. The list would be incomplete without Sanitary soaps, and the two specimens sent us are so designated from the fact of the one containing eucalyptol and the other carbolic acid, both in conjunction with glycerine. The moisture in all samples varied from only 5 to 6 per cent., the combined alkali from 9 to 10 per cent. There was no evidence of free alkali, nor was any substance detected which should not properly enter into the composition of good and well-prepared soap.

DEVONSHIRE CONFECTIONS.

(JOHN CLEAVE & SON, WEST OF ENGLAND STEAM CONFECTIONERY WORKS, CREDITON, DEVON.)

More need not be said than that these confections are made of the purest materials; and where colour had been used it proved to be on analysis of a harmless character. Of the varieties sent us the following are types:—Lorna Doone, a toffee said to be made from clotted cream; Cream Almond Rock; Chocolate Almond Nougat and Devonshire Cream Butter Scotch—all were of excellent flavour.

SALIPYRIN (TABELLÆ AND CACHETS).

(ALLEN & HANBURYS, PLOUGH-COURT, LOMBARD-STREET, E.C.)

As its name would indicate, salipyrin is a compound of salicylic acid with antipyrin; it contains 42·3 per cent. of the former and 37·7 per cent. of the latter body. Salipyrin is a white crystalline powder, free from odour, slightly acid and astringent to the taste, sparingly soluble in water, but readily so in alcohol. On heating on platinum foil it burns with luminous smoky flame and leaves no residue. The substance, we find, melts in a test-tube and gives off a small crystalline sublimate, while a smell of phenol and oil of winter-green is distinctly perceptible. Perchloride of iron gives, as with salicylic acid, an intense violet colour, and acetic acid and sodium nitrite, an emerald-green

Digitized by Google

colour distinctive of antipyrin; it is evidently, therefore, a loose compound. The production of salipyrin was the outcome of a suggestion to combine the antifebrile and analgesic properties of the base antipyrin with the anti-rheumatic action of salicylic acid. It is therefore very probably of value in cases where either or both drugs are indicated. Salipyrin has been largely employed in the treatment of influenza on the Continent, and we have recently learned of gratifying results following its administration at home.

THE PERFECTED COD-LIVER OIL EMULSION WITH HYPOPHOSPHITES OF LIME AND SODA.

(ALLEN & HANBURYS, PLOUGH-COURT, LOMBARD-STREET, E.C.)

This preparation is a well-made emulsion. It is quite tasteless as regards cod-liver oil, and possesses a very agreeable flavour. Under the microscope could be seen numerous and uniform-sized oil globules. Water dissolved out hypophosphites, and their presence was recognised by characteristic reactions. With zinc and sulphuric acid, for example, a gas was obtained smelling of phosphuretted hydrogen, and burning with a green-tinged flame. Sulphuric acid mixed with the emulsion produced a deep crimson colour. The preparation is doubtless a valuable one, and one which, as it yields highly satisfactory analytical results, we are glad to bring before the notice of the profession.

ESSENTIAL OIL OF EUCALYPTUS AND EUCALYPTOL.

(THE DOWNIE B. I. P. COMPANY, SAN FRANCISCO, 4, REDCROSS-STREET, LIVERPOOL, AND 80, BILLITER-SQUARE BUILDINGS, E.C.)

Eucalyptus is no new thing, but eucalyptus oil as a bye-product is a decided novelty. It appears that the above company discovered that a strong decoction of eucalyptus leaves is effectual in softening hard water for steam-making purposes and for preventing boiler incrustations. Eucalyptus decoction is said to offer distinct advantages over the ordinary "boiler compounds" at present in use—caustic alkali, for example. It is claimed to be, for instance, without action on iron. In the preparation of this extract the oil is of course obtained as a bye-product, and as such it compares, judging from our examination, most favourably with the specially obtained kinds. The specimen of eucalyptol commenced to boil, we found, at 160° C., and the whole distilled over at 170°. The specific gravity at 15° C. was 0·897. On evaporation a small residue remained. The essential oil distilled over between 170° and 180° C., and had a specific gravity at 15° C. of 0·906, and yielded a slight resinous residue on evaporation. Nitrous acid produced no reaction to indicate the presence of phellandrene. Both products are clearly of excellent quality.

PULVIS KUTNOVII ANTI-ASTHMATICUS.

(S. KUTNOW & CO., 66, HOLBORN VIADUCT, E.C.)

We have met with not a few preparations similar in substance to the above, which are offered as of value for the relief of asthma, bronchitis, &c. It consists of a dried herb of pleasing aroma, impregnated with a deflagrating mixture. The powder slowly deflagrates with scintillation when lighted, and gives off an abundance of smoky fumes. We cannot speak from clinical experience of its value; but as our examination shows that it is carefully prepared and contains ingredients of a selected kind, it may be deemed worthy of trial.

IODOPYRIN.

(BURROUGHS, WELLCOME, & CO., SNOW-HILL BUILDINGS, E.C.)

It may be of interest to record the following reactions yielded on experimental examination of this interesting compound. Heated in a tube, it melted, turned brown, and finally gave off violet vapours of iodine. The residue on cooling emitted a distinct odour of almonds. Chlorine displaces the iodine, as on the addition of the solution of this gas in water and a little starch emulsion a blue colour was produced. Carbon disulphide, too, dissolved out iodine on addition of chlorine water. No reaction could be observed when sodium nitrite, together with acetic acid, were added; but on boiling for some time with chlorine water, and then adding these reagents, the emerald-green colour characteristic of antipyrin was obtained. Iodopyrin, as its name implies, is a compound of iodine with antipyrin, and is represented by the formula, $C_{11}H_{11}N_2IO$. It is slightly soluble in cold water and alcohol, readily in hot, is tasteless and without odour. This interesting product, first prepared by Dittmar, is stated to be effectual in rapidly lowering the temperature and in promoting diaphoresis. In the stomach it is most probably decomposed into iodine and antipyrin.

LIGHT DINNER ALE.

(GOODMAN & YOUNG, STAMFORD-HILL BREWERY, STOKE NEWINGTON, N.).

The demand for palatable malt liquors, less full and less heavy in character, appears to be growing in this country. Light bitter beer has to a great extent replaced the once favourite heavy Burton or fourpenny ale, while lager beer has rapidly gained ground as a refreshing and wholesome beverage, especially during the summer months. The light ale under notice was found to resemble in composition, though not in flavour, ordinary lager beer. Thus, analysis showed 3·82 per cent. absolute alcohol by weight and 3·85 per cent. malt extract. (The well-known Munich beer contains 3·80 per cent. alcohol and 3·90 per cent. extract.) Malt and hops enter solely into the composition of the ale, and it seems well adapted for table use. *Apropos* of this subject we are prompted to ask why brewers generally have not succeeded in placing in the market an article equally refreshing and palatable as lager beer, and one that is calculated to quench thirst without producing muddled brains? Light beers, however, are more prone than the heavier kinds to turn sour or lose condition, and this probably has been the objection to their general production.

FAREWELL DINNER TO PROFESSOR SHERIDAN DELÉPINE.—On Saturday evening, the 23rd inst., a farewell dinner was given in the Café Royal, Regent-street, to Dr. Sheridan Delépine, on the occasion of his leaving London to fill the post of Professor of Pathology in Owens College, Manchester. Between fifty and sixty of Dr. Delépine's colleagues and friends were present. The chair was occupied by Dr. Dickinson, who had on his right the guest of the evening, and on his left Sir Andrew Clark, Bart., President of the Royal College of Physicians. Amongst others were present Dr. Lauder Brunton, Dr. Klein, Dr. George Harley, Dr. De Watteville, Prof. Anderson Stuart of Sydney, Dr. Woodhead, Prof. Victor Horsley, Mr. Watson Cheyne, Dr. William Hunter, Dr. Rolleston, Prof. Halliburton, Dr. Mott, Dr. Sherrington, and Dr. Sidney Martin. The chairman, in proposing the health of the guest of the evening, spoke in warm terms of the excellent work Dr. Delépine had done in London, and of the promise that he gave for the future. Whilst regretting his loss most deeply, it could not but be felt by all those present that the transition to Manchester would give him opportunities which he had not hitherto had, and of which he was sure Dr. Delépine would avail himself to the full, and he with all those present wished him and those dear to him all happiness in his future home and sphere of work. Dr. Delépine, in reply, spoke of the great kindness that he had always received from his colleagues, and of the heartiness of their support not only in his recent candidature but at all times. During the evening Dr. Lauder Brunton proposed the toast of "The Progress of Pathology," which was well received, and was replied for by Prof. Victor Horsley and Dr. G. S. Woodhead. Sir Andrew Clark proposed the health of the chairman, a toast which was cordially received. The remainder of a very pleasant and sociable evening was interspersed with songs and stories, which were highly appreciated.

THE LANCET.

LONDON: SATURDAY, JANUARY 30, 1892.

A MEMORANDUM has just been issued by the Local Government Board upon the precautions which are advisable at times when epidemic influenza threatens or is prevalent. It will be remembered that in July last an exhaustive report, prepared by Dr. PARSONS, on the epidemic of 1889-90, was issued by the Local Government Board, together with an introduction by Dr. BUCHANAN; and it was then explained that since effectual action for the prevention of disease must be based on a knowledge of its causation, and since but little was known of the natural history of influenza, advice as to its prevention must necessarily be very incomplete. It is admitted that this lack of information still very largely obtains; and it is significant that though influenza has prevailed in most parts of the world, no authoritative counsel as to its means of prevention has been published by any State.

In view, however, of the recurrence and maintained prevalence of the disease, the Board evidently feel that there may be advantage in setting out in a form easily procurable by the public a brief summary of those points as to which certain definite knowledge has been obtained. It is in the first place laid down that influenza is spread by infection from person to person. The report issued by Dr. PARSONS contained abundant evidence on this point; and Dr. BUCHANAN, reviewing this evidence, and admitting that the infection may possibly travel by some less direct means, expressed the opinion that in its epidemic form influenza is an eminently infectious disease, and that there can henceforth be no doubt about the fact. Circumstances constantly coming within our knowledge show that this important point is most imperfectly appreciated by the public, and we think that the quotations from Dr. BUCHANAN'S introductory chapter, which are embodied in the new Memorandum, will usefully draw fresh attention to the fact. One of the reasons why aerial diffusion, apart from human agency, has been so commonly regarded as accounting for outbreaks of the disease, has been the circumstance of the rapid spread of the infection simulating the operation of a single cause simultaneously on all who were attacked. On this point Dr. BUCHANAN has called attention to the fact that influenza having something like a third part of the incubation time proper to small-pox, measles, or typhus fever, it has correspondingly rapid ability to reproduce itself, and that it can thus give rise to some thousand attacks in the same time that small-pox or typhus fever would produce ten, each of the thousand cases being ready to infect other susceptible people.

This circumstance, and the absence of any such definite symptom as a rash—like that which accompanies some of the ordinary specific fevers,—tend still further to prevent the early and certain recognition of the complaint; and the consequence is that such preventive action as is practicable is often deferred until the cases have multiplied and the infection has already spread beyond control. These various considerations having been set forth in the memorandum by way of prelude, it is then explained that notwithstanding these difficulties, which stand in the way of the application of proper precautionary measures to the general population and to the breadwinners of a community, there still remain some circumstances under which certain preventive measures may be applied to certain classes of persons; notably to persons in whom an attack would be specially dangerous by reason of age or infirmity, to inmates of institutions whose mode of life can be regulated, and to first attacks in households, and even in certain localities. Amongst these measures isolation stands foremost, and it is stated that measures to maintain separation between the sick and the healthy have in some instances been adopted with marked success. The methods in which the isolation is to be applied must necessarily vary, and it must be admitted that isolation in hospital by sanitary authorities can hardly be contemplated. Next to isolation the disinfection of infected clothing, of other articles, and of rooms is advocated. It is also urged that persons suffering from influenza should not expose themselves in public places.

By way of guide in the carrying out of these measures we may recall the fact that, according to Dr. PARSONS' report of last year, evidence has for some time past been available to the effect that the disease is infectious at quite an early stage, and that it may remain so as late as at least the eighth day from the attack; and it is now added that evidence to this effect has since accumulated. These points deserve consideration in connexion with a further recommendation that the assemblage of large numbers of persons in a confined atmosphere should be avoided. The incidence of the disease on members of the House of Commons, on the inmates of certain institutions, and on persons shortly after attendance at crowded meetings of various sorts must be within the knowledge of most people; and it should be remembered that in persons ill fitted to withstand the disease even ordinary aggregations might properly be avoided during periods when influenza threatens or is prevalent.

A second point to which prominence is given in the memorandum is that the liability to contract influenza, and the danger of an attack, if contracted, are increased by depressing conditions, such as exposure to cold, or to fatigue, whether mental or physical; and advice follows as to the maintenance of a good standard of health, as to the wearing of clothing of suitable warmth, and as to the taking of wholesome food. The need for restoratives at a certain stage of the disease has led some to resort to alcohol as a mere preliminary preventive. This is as great a mistake as the sudden abandonment of a reasonable and customary amount of alcohol. As the result of the former practice, not only does this stimulant become of little avail at a time when it might be otherwise helpful, but the power of resistance to the infection is distinctly lessened in advance by any improper and exceptional resort to stimulants; and hence the memorandum, in dealing with precautionary measures, utters a timely warning against anticipating influenza by any excessive use of alcoholic liquors. Advice is also given with a view to the avoidance, amongst those

Digitized by Google

attacked, of the pulmonary complications which constitute a chief danger of the disease. Thus it is especially urged that those suffering from influenza should studiously avoid anything which involves exposure to cold or fatigue; and a final caution is issued to the effect that persons who find themselves attacked by the malady should not attempt to fight against it; but should, on the contrary, seek rest, warmth, and medical treatment.

Some of our contemporaries have recently been urging the Government to give advice to the public as to the proper treatment of the disease. But this has never been a function of the health department of the State in this country, a department which has concern with the prevention of disease and with the maintenance of the health of the public, not with the medical treatment of individuals, a matter which must remain the duty of those who, by actual observation of the sick, can alone judge what are the remedial measures called for in one and another patient. Holding this point in view, the document concludes with the statement that the nature of the treatment of cases of influenza does not fall within the scope of the memorandum.

THE trial STEELE *v.* SAVORY was held on Tuesday and Wednesday last before Mr. Justice ROMER, when, as our readers will perceive from the report of the proceedings which appears upon another page, the plaintiffs claim was disallowed and the relief sought refused, while the position taken up by the Council of the College was vindicated upon all the points brought into issue in the proceedings. It is therefore a matter of some moment that the issues involved, and consequently the effect of the decision reached, should be clearly understood; for it cannot be hoped that the action in the Chancery Division will set at rest the controversy of which it was but an outgrowth, and it is therefore desirable that its bearing upon any future discussion should be clearly and accurately apprehended. The substantial question tried, as we understand it, was—Have the members, in spite of By-law xvii., any right to meet in the hall of the Society which does not depend for its exercise upon the approval of the governing body of the College, and which it would be a breach of duty on the part of the Council to deny? The larger question, which has been the subject of annual discussion since 1884, is a question not of what is, but of what ought to be, the measure of the Members' rights. This, however, is a question upon which no court of law or of equity has jurisdiction to enter. It occurred a few months since to some of those who have stood in the forefront in this dispute that it might be possible to make out, not merely that Members had an abstract right to an increased share in the administration of the College, but also that they had a legal claim to some part—a small but still a substantial part—of the enlarged functions which they desire to exercise. They took steps to assert this claim, and by a course of conduct fully justified upon their own view of their rights, but unwarranted upon the view which the Council took of the same matter, they placed themselves in a position which compelled the Council to deny their claim, and then proceeded to assert it by legal means. The claim which thus became the subject of contention was a claim to use the College hall for the purpose of a meeting to discuss College affairs. It was formulated by the counsel who appeared in support of the Members' case as a claim of the right to the reasonable use of the hall of the College for all proper corporate purposes. The contention, on the other hand, was that the only purposes for which it could be used by members were purposes of which the Council of the College had signified approval. There, reduced to its smallest compass and most concrete form, lay, as we understand it, the whole matter in debate in the Chancery Court.

The right so contended for is of itself a matter of very great importance regarded from either point of view, but its inherent importance was strictly subordinate to that of the principles upon which it was determined. Without attempting to repeat or even to recapitulate the argument which is summarised in our report, we may indicate that in behalf of the Members it was asserted not only in opposition to the by-law, but also, if necessary, in opposition to the Charter under which the College is incorporated, on the ground that it had been given by Act of Parliament, and could not be taken away by anything less than a repealing Act. It was in view of this contention that the ancient history of the surgeon's craft in London was elaborately set out in the statement of claim. This contention was, however, met by a recital in the Charter, under which all the subsisting Members have indisputably been admitted, to the effect that the company to which these grants were made by the Act of Parliament had become dissolved. In the course of this discussion the curious position was reached in which the malcontent Members were contending for the antiquity of the College, while its governing body was saying, on the other hand, that it was an institution of recent creation which came into existence only in the year 1800. In the end, the view advanced by the governing body was adopted by the Court, and the College held to have taken its origin from the Charter of GEORGE III. The rights, therefore, which members of the Surgeons' Company might have claimed were held not to enure for the benefit of Members of the existing College, who are thrown back upon their own charters. Upon a consideration of these documents the Judge arrived at the decision that there was power in the Council to make the by-law that had been impeached, and power also to enforce its observance by the sanction of expulsion. It is therefore clear that, upon the basis of the law as laid down by Mr. Justice ROMER, the plaintiff Members of the College have much overstated their legal rights. The object of their desires is not to be sought at the hands of the judicature, and although the decision reached on Wednesday last does not in any way touch the merits of the controversy, it goes to show that in this dispute the Council are not aggressors, maintaining ground which they have occupied without the warrant of a title to the position, but that, on the contrary, they are merely defending a legally sound position, and that if any change is to be hereafter brought about in the status of the Members, it must result from legislative action. The Crown has already refused to confer a fresh Charter in opposition to the wishes of the governing body, and the reason is doubtless a perfectly valid one. But Parliament

Digitized by Google

can listen to any complaint, from whomsoever emanating. It is possible, and we should be glad to think that the fact would be so, that both parties may after this episode be disposed to resume the discussion with an enhanced desire to arrive at an agreement. If that could be effected, there seems to be no room for doubt that any settlement which might be adopted by consent would easily receive the necessary authorisation, and so acquire the force of law.

As will be seen, we have in the above remarks simply set forth the matter from the legal point of view; its professional aspect must be dealt with in another article. We understand that the case may not improbably be taken to a higher court.

DIABETES has long been a favourite field of investigation for the physiologist and pathologist as well as for the physician. The remarkable perversion in the normal process of nutrition which this malady exhibits has done much to rivet attention and to lead to frequent inquiries into its precise pathogeny. The flood of light shed upon the subject by the revelation of the glycogenic function of the liver—to which CLAUDE BERNARD and PAVY contributed so largely—and the striking discovery by the first-named of the production of glycosuria by puncture of the fourth ventricle, have served to point the way to many fresh lines of research and to suggest the direction in which the causative conditions of the disease may perhaps be found. Nevertheless, in spite of all this labour, full and fruitful as it has been, there has remained behind a sense of something still to be discovered before the true explanation of diabetes can be attained. It is something to have conceived of glycosuria, as apart from diabetes, but the various types of the disease itself seem to demand a more thorough analysis than has hitherto been attempted. The revival within the past year or two of the notion that the pancreas may be the organ at fault is one indication of the indeterminate state of the subject. That this notion is a revival of an old doctrine must, we think, be admitted. Long before anything was known or suspected of hepatic glycogenesis morbid anatomists had from time to time observed manifest organic changes in the pancreas of diabetics. These changes comprised conditions of atrophy and fatty degeneration, of induration and chronic inflammation; but their frequent absence led them to be considered less as causal conditions of the diabetic state than as coincidents. Still, the concomitance seemed to be too frequent to be merely accidental; and unless it could be shown that the changes in the gland were really secondary to the general nutritional disorder, it was fair to surmise that they might have some share in the production of the latter. It was M. LANCEREAUX who first formulated this idea of a "pancreatic" as distinct from a "hepatic" diabetes, and averred that the former was characterised by a more rapid course, with extreme emaciation, than the ordinary class. Nearly twenty years ago, at the London Pathological Society, the late Dr. SILVER exhibited a specimen of extreme fatty degeneration of the pancreas from a case of diabetes,[1] and mentioned that of thirty examinations of diabetics ROKITANSKY had found this organ diseased in thirteen; and at the same meeting Mr. COUPLAND mentioned his observation of an extremely cirrhosed condition of the pancreas in a case of diabetes and phthisis.[2] These and similar observations are, however, comparatively isolated, and even the subsequent discussion at the same Society upon the morbid anatomy of diabetes[3] failed to elicit much information; but in his more recent Bradshawe lecture Dr. SAUNDBY showed that in many cases there was some reason for associating the morbid changes found in the pancreas with diabetes.[4]

The evidence in favour of a pancreatic form of diabetes as afforded by morbid anatomy does not appear to be conclusive, but when taken in conjunction with recent experimental data, it gains greatly in importance. Extirpation of the pancreas is, from the position and relations of the organ, an operation of considerable difficulty and danger, and the earlier experiments by BERNARD and others gave no satisfactory result. It was, however, determined that mere ligature or occlusion of the pancreatic duct had no effect so far as regards the production of glycosuria. In 1889 Drs. MINKOWSKI and VON MERING reported to the Medical Congress at Heidelberg the results of their experiments on ablation of the gland, observations which they have since extended and confirmed. These observers found that total removal of the organ was followed by a permanent glycosuria, with wasting and other phenomena of diabetes, and subsequent death, results which did not follow partial extirpation or ligation of the duct. These observations attracted much attention, and were the starting-point for others of a similar character, notably by M. LÉPINE, M. HÉDON (who reviews the whole question in an interesting article on "Diabète Expérimental" in the supplement to the *Montpellier Médical*, Jan. 1892), M. GLEY, and Dr. VAUGHAN HARLEY.[5] The sum and substance of all these experiments amount to this—that glycosuria, and, if there be a sufficiently long survival, a true state of diabetes, ensue upon total extirpation of the pancreas, whereas such a condition is never established if only a small portion of the gland be left intact. The explanation afforded by M. LÉPINE of these phenomena is interesting. He avers that the pancreas, like the liver, has a double function. Its office as a digestive gland, secreting a special ferment for that purpose, is not its sole duty. Its cells, which are disposed in relation to bloodvessels quite as much as to the excretory ducts, have also the property of forming a special *glycolytic* ferment, which finds its way into the blood, and is employed in destroying the sugar therein. He thinks that the leucocytes take up this ferment, and one writer hazards the suggestion of its alliance with the fibrin ferment that these corpuscles contain. So long as any gland cells are intact and capable of producing this ferment, glycosuria will not occur; but when they are entirely removed, the glycolytic action ceases, and glycosuria results. All this is purely hypothetical, for the ferment has not been separated, although the analogy with the liver is highly suggestive. As to the competence of small and residual parts of the gland which still retain their vascular connexions to ward off the occurrence of diabetes, it is

pointed out that in the case of the thyroid "cachexia strumipriva" does not happen unless that body is entirely extirpated. Whether this ingenious hypothesis be substantiated or not, it does seem clear that a certain number of cases of diabetes may be linked with destructive lesions of the pancreas, which entirely inhibit the functions of the gland. Dr. VAUGHAN HARLEY has recently[6] recorded two cases of pancreatic diabetes observed by him at Christiania. One, exceptionally acute, was allied with suppuration of the gland; the other, of much longer duration, with cancer, which, it may be remarked, has not usually been observed to be associated with glycosuria.

In his paper read at the Royal Medical and Chirurgical Society last Tuesday, Dr. H. J. TYLDEN ventured to dispute the inferences drawn by M. LÉPINE from experiments and also those afforded by morbid histology. Granting the existence of a glycolytic ferment in the blood, he objected that its diminution in diabetes might only be a secondary phenomenon, and that clinical experience pointed more in favour of increased production of sugar in diabetes than to a diminished power of its destruction. Moreover, he was inclined to attribute the results of total extirpation of the pancreas to extrinsic lesions incidental to the severe operation. It is curious, however, that in such experiments as those of HÉDON—where the pancreas was removed in portions—no glycosuria occurred until after the last fragment was removed, although the severity of the earlier operations must have been as great as the last. In the debate that followed the reading of Dr. TYLDEN'S paper it will be seen that Dr. BRADFORD adduced strong grounds for accepting a pancreatic diabetes from the physiological standpoint, and Dr. GEORGE HARLEY from the clinical side; whereas Dr. ROLLESTON inclined to Dr. TYLDEN'S opinions, and even hinted that pancreatic lesions might influence hepatic functions through the nervous system. Dr. TYLDEN has done good service in studying the morbid changes in the pancreas, and especially its cirrhotic condition, which he shows to be by no means confined to diabetes; but then it must be remembered that there may be changes in organs capable of profoundly influencing their functions which may escape the closest scrutiny. At any rate, we do not think that the study of the pancreas in relation to diabetes should be too lightly abandoned now that it has received such important aid from experimental physiology.

THE Draft Charter for the new teaching university in London as passed by the Lords of the Privy Council will be laid on the table of both Houses of Parliament on their reassembling on the 9th prox. It must remain there for a month; in six weeks, therefore, we shall know whether the Charter for what would probably be, under its provisions, the largest medical university in the United Kingdom will be granted. It is evident that considerable opposition will be made to its passing through the House of Commons, and an attempt to refer the whole matter back to the Royal Commission is being made. This attempt, if successful, will prevent any settlement of the questions for the present generation, and will serve to reopen the old controversy which rendered invalid the action of the Senate of the University of London. The opposition against the provisions in Arts is more formidable than that raised against the medical portion of the Charter. Many members of the University of London still fear that the new University may in some way damage the work and prestige of the older institution; but as a collegiate training of two years is insisted on in the case of students from other universities, it is not easy to see that there can be any marked clashing of interests, especially if the existing University maintains an open portal and its present examination standard. It cannot be supposed that, in the face of this regulation in the case of students from other universities, the Council will lay down a shorter course for any of its own students. The complaints as to the non-recognition of University extension lectures, evening classes, and other similar lectures at various places have been made in ignorance of the fact that the collegiate training, if it is to be of any good, must ensure a long and regular course of study, as in the case of a medical student, for whom a five years' curriculum is now made imperative. Another objection, which will carry more weight in the minds of many, is that King's College is an institution whose professors, with scarcely an exception, necessarily belong to the Church of England. But most people who have spoken or written on this line have lost sight of the great preponderance of the medical element on the Council, and argue as if the two teaching colleges—University and King's—alone formed the University. Out of a council of forty members, only three will be direct nominees of King's College. A stringent clause prevents the imposition of any religious test by the Council of the University. The great representation is in the hands of the teachers in the medical schools, for seats are provided for at least fourteen. Most of the objectors have forgotten that it is mainly in the interest of the London medical student, and to give him privileges similar to those now given at the other centres of medical teaching, that this University has become a necessity. Side by side with the medical grievance the movement for a University in which the teachers should have a practical control has also found great support. So for two defects in the existing University of London a remedy has been found. If a medical university alone were possible, the Royal Colleges would probably have succeeded in forming such a one; but it was only by an alliance with the teaching Colleges that faculties of arts and science could be established, and a full University scheme be thus secured. The objections to the medical clauses are chiefly made by the authorities of the Victoria University, and appear to us to be very ungracious and uncalled for. The medical students of Manchester, Liverpool, and Leeds have the usual facilities for obtaining degrees, whilst the students in London have none, save on conditions which are prohibitive except to a small minority. The plea is immediately put forward that the London teachers will unduly lower the conditions on which the new degree shall be given, and specially depreciate the training of the medical man in arts and science. But surely if the professors at Manchester could be trusted when their Charter was granted, the London teachers are entitled to have the same confidence placed in them. We suppose that on the first council of the new University members will be found who will be quite as anxious for the good name of

[6] Brit. Med. Journ., Jan. 2nd, 1892.

Digitized by Google

the degrees of the new University as is the case at the other universities. But this objection as to the depreciation of the degrees is merely a device put in the front in order to support the real apprehension of the northern teachers. They object to the clause requiring two years' residence at the final part of the curriculum, which they think will draw men from the northern schools to the London centres of clinical instruction. We question whether the Victoria University will be affected more than any other university, but, if so, the remedy will be in their own hands. If the clinical teaching be better in the provincial schools than in those of the metropolis—and it can be improved in both—the students will very quickly recognise the fact, and will not desert a school near to their homes, and at which they have already studied, for a distant one where the instruction is inferior. Such jealousy ought not to influence the Houses of Parliament any more than similar complaints from Edinburgh and Dublin influenced the Lords of the Privy Council, before whom the Victoria University should also have lodged their objections. A circular letter, signed by the heads of King's and University Colleges and the Deans of the Medical Schools (with the exception of St. George's and Westminster Hospitals), has been sent to all the metropolitan members of Parliament asking for their support, and we trust that the solution of the medical difficulty in London, which offers the only hope for the present generation, will not be frustrated on a side issue.

Annotations.

"Ne quid nimis."

THE PREVENTION OF INFLUENZA AND OF MEASLES.

A CURIOUS misapprehension of the real facts with regard to the prevention of measles is being put forward by means of letters and other contributions addressed to a number of our contemporaries by way of comparing this disease with epidemic influenza. The point is put forward as significantly as anywhere by Dr. Frank G. Clemow in a letter to *The Times* of Jan. 25th. He draws a comparison between influenza and measles as regards the non-discovery of their cause, and here he is unquestionably right. He next compares them in regard to the results of isolation by saying of measles, amongst other diseases, "these are well under control," and he then asks, Why should not the same be done for influenza? Here he, with others, falls into error. We have again and again pointed out that the measles mortality in this country is not only enormous and apparently all but uncared for; but that instead of its being under control it is steadily increasing, and that but little effort is made to ascertain the causes of this increase. Over 13,000 lives are annually sacrificed directly to measles in England and Wales; and not only so, but whereas in the ten years prior to the passing of the Public Health Act, 1875, with its provisions as to isolation, the mean rate of mortality from measles was 401 per 1,000,000 living, it has risen during the decennium 1881-90 to 440 per 1,000,000. This rate exceeds anything that can thus far be directly attributed to influenza; but whilst panic arises about the disease the fatality from which is so notable amongst the well-to-do and the aged, the terrible death-roll from measles, which has its incidence especially on the infantile population amongst the lower classes, passes all but unheeded.

OATH ADMINISTRATION IN COURTS OF LAW.

SINCE the appearance of the letter from our correspondent "L." in last week's issue of THE LANCET we have had an opportunity of perusing the Act to which he referred and of verifying the statement he made. The Act is, in its full title, An Act to Amend the Law as to Oaths, and shortly, the Oaths Act, 1888. It appears to be very little known, but is important as providing not only the alternative alluded to by "L.," but also the affirmation for those who have no religious belief, and those who object to the taking of an oath as contrary to their religious belief. Clause 5 is precisely as "L." gave it, and may be repeated here: "If any person to whom an oath is administered desires to swear with uplifted hand, in the form and manner in which an oath is usually administered in Scotland, he shall be permitted so to do, and the oath shall be administered to him in such form and manner without further question." The Act is a very short one, and may be obtained from Messrs. Eyre and Spottiswoode, the Queen's Printers, for the sum of one halfpenny. Many will no doubt avail themselves of this preferable mode of adjuration, and possibly it may come to be generally adopted.

THE LOCAL GOVERNMENT ACT OF 1888 IN RELATION TO ASYLUM AUDITS.

DR. CAMPBELL, medical superintendent of the Counties Asylum at Carlisle, has sent to us a reprint from the current number of the *Journal of Mental Science*, in which he deals with "The Local Government Act of 1888: its Probable Action on the Treatment of Insanity in England." It appears that the auditor at his first visit after the Act was passed "surcharged" one item, a gratuity of £10 to an attendant. At his second audit, five months later, he surcharged three gratuities—namely, one of 8s. for bringing back an escaped patient, another of a sum of £823 for attendants' pay because their names and rates of pay had not been fully entered on the minutes, and another of a sum of £51 given in three grants, one to a dying attendant, the other two to deserving attendants who resigned for special reasons. Dr. Campbell has been apparently singularly unfortunate in this matter, as his asylum is the only one out of eighteen county asylums which have given gratuities since the passing of the Act, where the auditor has surcharged such payments. He naturally objects to this question being left to the caprice of asylum auditors, and contends that, if the giving of a gratuity is illegal, it should be so for all. There are, as he says, frequently circumstances occurring in asylums in which, in the interest both of the institution and its inmates, sane and insane, it is almost a necessity to give a gratuity or extra pay for special actions. In the absence of any reason for disallowing the gratuities referred to, we agree with Dr. Campbell that the auditor in this case seems to take a most severe view of the subject. There are unquestionably risks of evils arising from any extensive system of gratuities, but that is not the point. If, in their collective wisdom, the asylum authorities are of opinion that a gratuity has been earned, and is the most desirable method of rewarding special service, and sanction its being given, we think an auditor ought not to interfere with that sanction except on very strong grounds, since they do so at a great risk of interrupting the efficient and beneficial working of an institution of this type. In this sense must Dr. Campbell be understood when he says that whatever deals with the treatment of the patients in English county asylums deals practically with the treatment of the insane

Digitized by Google

in England. "The Local Government Board," he continues, "no doubt have the power to authorise such necessary grants as those referred to, even although no special provision may be found for them in the law, or they can indicate the legal and proper mode of making such payments."

THE SALE OF DISEASED MEAT.

IT is not often that we have to deal with a case of such flagrant and dangerous abuse as that in which an Edinburgh butcher was recently convicted of selling for food the flesh of an animal which had died of anthrax. Here there could be no doubt as to the justice of the sentence. The virulence of anthrax contagion, even after the death of the affected animal, has been abundantly proved. In this case it was again conclusively shown by the fact that a man inoculated by the diseased meat had died in consequence. Let us but glance at the risks incurred by any who might in perfect ignorance have purchased it at the butcher's counter, at the possible effects of handling it with skin-cracked hands perhaps, or of eating it under-cooked as a juicy steak, and we shall not fail to share the regret expressed by the presiding sheriff, that the circumstances of the prosecution did not allow of imprisonment without the option of a fine. It were well, in our opinion, if the requirements of law in matters of this kind were made even more stringent than they now are. There is usually something unnatural even in the so-called natural death of an animal. Unless in such exceptional conditions as death by accident or from asphyxia consequent on over-fattening, an antecedent pathological state injuriously affecting the quality of the meat may be taken for granted, and this fact is rendered the more significant by the difficulty of effective depletion by bleeding. In this connexion we might learn something from the Jewish Code, which, with wise, if excessive, caution, condemns as unfit for food the animal which has died "of itself."

PROFESSOR CELLI ON WOMAN'S PLACE IN SOCIAL HYGIENE.

AT Rome, on the 10th inst., in presence of Her Majesty the Queen of Italy, the accomplished occupant of the chair of State Medicine in the Sapienza addressed a brilliant audience on woman's place in social hygiene. Professor Celli turned to excellent account his experiences in Great Britain at and after the International Congress in August last, and showed his Italian hearers how much can be effected by organisation in fields so vast and so diversified as those of sanitary and social reform. There were many among his audience of ladies who had nothing to learn in the matter of enlightened and energetic work for the benefit of the sick and needy; many of them, it is safe to say, from Queen Margaret herself downwards, whose lives were honourable examples of self-sacrifice in the relief of suffering and misery. But something more is required than individual initiative and individual exertion, however well-directed and however exemplary. Beginning with Lady Mary Wortley Montagu, Professor Celli traced in vivid and impressive outlines the story of woman's work in the hygienic rehabilitation of England, dwelling at considerable length on the Ladies' Sanitary Association, founded in 1857, and following it up and out into all its beneficent ramifications to the present hour. On one point he laid particular stress, and that was the popular literature issued under the auspices of the Association, literature setting forth in an easily understood and attractive form the main factors of personal and public well-being, and contributing to that most desirable consummation by which (in the words of Sir James Coxe) "every individual shall be taught to become the intelligent custodian of his own health." By thus indoctrinating the future generation, particularly the wives and mothers, in all that conduces to a healthy and normal life, there is prepared that public opinion which is so sorely desiderated in the Latin races, and nowhere more than in Italy, whereby pressure is brought to bear on municipal and central authorities, and abuses corrected and reforms insisted on which hitherto have been preached and prayed for in vain. From England Professor Celli passed to Germany, and enumerated the salutary innovations in public, and particularly in school hygiene, promoted, if not initiated, by the Empress Frederick; and thereafter, having reviewed the sanitary position of France, he concentrated himself on the wants of Italy, whose numerous local and private charities were so many foci capable of being fused together till something like a "Ladies' Sanitary Association" was reached. Drawbacks and difficulties there were, as he amply admitted—impediments due to the special circumstances under which Italy had wrought out her political redemption. Heavy taxation, restricted means, backward education, were conspicuous among these. But they would all yield to time and to persistent organised effort. "On you, the women of Italy," Professor Celli concluded, "rests the moral and physical regeneration of Italian youth. To achieve this you have not a day to lose, not a sacrifice to spare. In the combat for humanity there are posts innumerable. Those among you who are not pre-engaged in the hallowed sphere of the family will assume the place of honour. Let each select her part, her corner, great or small, according to her strength, her aptitude, her vocation; let her consider it as a sacred duty to give of her means or her abilities to fortune's disinherited ones. And so, when from the luminous examples of female forethought and heroism which honour your sex and our common country, emerges the collective power of an educative charity, you, not by calculation or in self-seeking, but by spontaneous instinct and sentiment, will become one of the most vigorous of the healing forces (*forze medicatrici*) of social well-being." An eloquent appeal to the sovereign under whose presiding favour the audience had assembled closed Professor Celli's opportune and inspiriting address, the fruits of which we hope to see one day manifested not only in the *classi diseredati*, but throughout the whole life of Italy.

A LESSON IN PREVENTIVE MEDICINE.

PROFESSOR W. T. GAIRDNER has done good service in publishing a paper which he read before the Association of American Physicians in September last, and which tells the story of certain arrangements made in Glasgow in 1866 with a view to the prevention of cholera. At that time Dr. Gairdner was medical officer of health for the city, the sanitary condition of which led him to look with grave concern on the possible advent of cholera, the more especially because of the terrible results of that disease in previous epidemics, and notably in 1854. Between the latter date and 1866 one change of immense importance had been effected—the Loch Katrine water had been introduced into Glasgow, and its use was at once extended where this was necessary. To cities having sources of water-supply liable to excremental pollution the contrast between cholera in Glasgow in 1854 and in 1866 is of great significance. But the sanitary state of the city was in other respects very defective, and typhus fever told the tale in terms that seem almost incredible to those who have only known Glasgow after many years of such labours as have since been bestowed upon it by Dr. J. B. Russell and his staff. Hence cholera was dreaded, and, above all, Dr. Gairdner feared the effects of panic, which might result from a sudden outburst which had already gained ground on account of unknown attacks of choleraic diarrhœa. How

Digitized by Google

were the inhabitants to be so dealt with in detail as to avoid such calamities? The question was solved by a chance encounter with a clergyman who at once declared that the Church workers would band themselves together as an organised body for the purpose "as volunteers." The hint was taken by Dr. Gairdner. Within a brief period every Church, regardless of differences of creed, supplied its volunteers; from these the workers were selected with care until between 3000 and 4000 "intelligent and active visitors" had been chosen, and shortly every home, every head of family, and every householder knew in advance what to do in case suspicious symptoms arose. They were urged to promote ventilation and cleanliness in their houses and tenements, all was prepared to meet an emergency, and confidence was instilled. Dispensaries, hospitals, and nursing arrangements were also set on foot; and when at last cholera came, it was limited to about sixty-six cases of true cholera and a few hundred of choleraic diarrhœa in half a million of people. The visitors were, as stated, volunteers, and gave their services "for the love of God." But still, a scheme to save Glasgow from cholera could not be set on foot without some substantial expenditure, and in the Scotch city, as everywhere else, there was at least one ready to complain that, though a key had been bought to lock up the horse, the cost had been thrown away, since the horse had never been stolen. "An eminent citizen of Glasgow," says Dr. Gairdner, complained "that after all the fuss made about the cholera, and all the expense incurred in its prevention, 'the cholera did not come.'" Similarly "eminent" citizens are unfortunately to be found on most town councils and other sanitary bodies.

THE VALUATION OF INSANITARY PROPERTY.

AN important judgment has been delivered in the Queen's Bench Division in the case of "Gough *v.* The Mayor and Corporation of Liverpool," in connexion with the valuation of insanitary property. The case has several times been before courts of law and before the arbitrator, the point in dispute being the basis on which an owner should be recompensed whose property was condemned as unfit for human habitation. The decision now given by Justices Lawrence and Wright is one that will materially assist in the removal of such properties without subjecting the ratepayers to the burden of paying compensation which is unreasonable in amount. Briefly stated, the judgment declares that an arbitrator ought not in such cases to take into account solely the amount which could be extorted by rent from people who were obliged by the necessities of their work to live in the neighbourhood in question; but that he ought also to take into account the sanitary condition of the property and the amount that would have to be expended in making it decently habitable. Thus the corporation are at last supported in their contention for a principle which is of great importance.

FUNCTION OF THE HAIR TUFTS IN MAN.

IN the January number of the *Journal of Anatomy and Physiology* Dr. Louis Robinson formulates a theory to account for the persistence in man of the tufts of hair usually present in the axillæ and over the pubes. These he imagines to be the persistent remnants of hair-tuft developed with reference to the clinging or grasping power of the young, and as a means of enabling them to cling to the parent, when he or she, as the case might be, was not in a position to spare an arm without much imperilling the chances of escape or rendering movement difficult. Naturalists have observed that young apes hang beneath the body of the mother and sustain themselves by grasping the hair, and it is stated that certain male gibbons assist in carrying the helpless young. It is an interesting point that in these apes the period of immaturity is prolonged almost as much as in man. Other considerations which Dr. Robinson looks upon as supporting his theory are the appearance of the hair at puberty, its appearance in both sexes, and the fact that it often appears earlier and more plentifully on the female. It also exists in parts where the young of tree climbing animals could attach their hands without danger of violent contact from obstacles, and Dr. Robinson has ascertained by measurement that in most cases the situation of the axillary and pubic tufts is within easy reach of the hands and feet of infants when their limbs are extended, if the body of the adult is in the position taken by that of an anthropoid ape in climbing. The theory is no doubt ingenious; but objections to it readily occur. Dr Robinson considers some of the most obvious of these, such as the existence of similar hair elsewhere and the sensitiveness exhibited by the skin when the hair in those parts is pulled. These, of course, are capable of being explained; but the theory would be very much strengthened if any example could be quoted of an anthropoid ape in which these tufts are actually used in the manner suggested by the author. Their development, if the theory is correct, must have been very much greater in his ancestors than it is in man at the present time to account for their persistence now, not only in the absence of any use for them for so many ages, but actually in spite of very considerable drawbacks to their existence, such as must exist in the friction to which they are exposed.

THE VENTILATION OF SLEEPING APARTMENTS.

AN important point in sanitation was discussed last week in an action brought before a county court in the eastern counties. The suit was one instituted by a master to enforce payment of £10, the remainder of a premium due to him by a father for apprenticeship of his son, but withheld on the ground of failure to provide suitable board, lodging, and business training. The question of chief interest in connexion with the case was that of sleeping accommodation, and the facts elicited were the following:—From the beginning of his apprenticeship the lad had slept in a room affording about 440 cubic feet of space, which had formerly been used as a store closet. There was no direct communication whatever with the outer air, but the door and the solitary window above it opened into a passage in the interior of the house. In this passage were the entrance doors of two crowded work-rooms, which were often occupied till a late hour at night. Opposite the door of the closet was the single window by which (provided it was open) the passage communicated with the outer air. It was contended by the defendant that here the arrangements for ventilation were faulty and injurious to his son's health, and that in effect the air which commonly entered the sleeping closet was that which escaped from the well-used work-rooms. The quality of this atmosphere may be imagined. Medical evidence was tendered by both parties in this action, with the result that on one hand the closet bedroom was freely condemned, on the other it was considered "undesirable," but still not such as to cause in a healthy occupant the signs of nervous weakness from which the boy was by general admission suffering, and it was, moreover, such a room as some poor families were known and allowed to inhabit. Guided apparently by the terms of this evidence, the jury gave a verdict for the employer. We must confess that we cannot agree with their decision. The cubic space allowed, inadequate though this was, might, after a fashion, have sufficed had other conditions been healthy. When, however, we find the standing rule that every sleeping apartment must have direct communication with the outer air completely ignored, we need not be at a loss to account for the nervous and general weakness

Digitized by Google

of its half-smothered inmate. We cannot doubt that the wan, anæmic, and exhausted aspect so characteristic of young *employés* in many town shops and warehouses is the direct result of this very lack of a pure atmosphere as much as of overpressure. It would, therefore, be a subject of lasting regret if a decision like that above mentioned should ever be suffered to acquire the force of a legal precedent.

SMALL-POX AND DEWSBURY WORKHOUSE.

ON several occasions during recent years the practice of the Dewsbury guardians to turn one of the workhouse buildings into a small-pox hospital has led to the spread of the infection to inmates of the infirmary, and, as we have noticed, this has been strongly condemned by the Local Government Board. At last that Board has informed the guardians that unless they at once receive a definite assurance that the practice shall be discontinued, they will issue an Order prohibiting the reception of small-pox cases within the workhouse. The action of the guardians still seems uncertain, for they say in answer that some of the statements contained in the report of the Government inspector were inaccurate, and they ask some explanation concerning the authority on which they were made. Whatever information may be forthcoming on this point, it cannot justify the exposure of helpless and sick paupers to the poison of small-pox in the workhouse, and it is to be hoped the Order will be at once issued.

GASTRIC ULCER.

THE causes of round ulcer of the stomach have been studied by Dr. Shcherbakoff of Moscow by means of experimental observations of dogs, with some interesting, though not very decisive, results. Loss of substance depends as a rule upon impaired circulation, but such loss of substance has a great tendency to be replaced. In order that a true ulcer may result there must be other favourable conditions, as an increase in the acidity of the gastric juice and a diminished resistance of the tissues. This fact, which has been deduced from clinical experience, has not hitherto been subjected to experimental verification. Dr. Shcherbakoff produced artificially a loss of substance in the stomachs of forty-five dogs by injecting an emulsion of chromic acid into one of the short gastric arteries. The loss of substance produced was precisely similar to a recent round ulcer, but in about five days cicatrisation began, and was complete in two or three weeks. In some cases within a week after the injection definite quantities of hydrochloric acid were introduced through gastric fistulæ; in other cases small quantities of aniline or pyrogallic acid were introduced into the stomach, or repeated bloodletting was practised before the injection of chromic acid, and the alteration of the blood induced by these methods was maintained by their repetition. In all these experiments ulcers were produced, and in some perforation occurred. With aniline also loss of substance was produced, even when no chromic acid injection was made. In order to solve the problem of the relation of the disease to impairment of the blood, observations were made on the changes of alkalinity in the blood and of acidity of the gastric juice. It was found that aniline reduced the alkalinity, but no relation between this reduction and the progress of the ulcer could be detected. Injections of pyrogallic acid and bloodletting did not definitely reduce the alkalinity. All these methods, however, increased the acidity of the gastric juice, and of course at the same time diminished the resisting power of the tissues, which diminution, however, is not to be considered as mainly due to the decreased supply of blood, but to the impairment of the whole of the vital conditions. Further experiments were made by introducing hydrochloric acid in definite daily quantities subsequently to the artificial impairment of the blood, but without any chromic acid injection. In the first case the animal died on the sixth day; several ulcers were found, one perforating. In the second case the animal was killed on the twenty-first day; superficial losses of substance of the mucous membrane were found. In the third case the animal died on the twenty-fourth day from a perforating ulcer. In all these there was a marked reduction in the alkalinity of the blood. It therefore appears that decreased alkalinity of blood due to impaired nutrition, together with increase of acidity in the gastric juice, form highly favourable conditions for the development of gastric ulcer. But, in addition to these, there are, in Dr. Shcherbakoff's view, a number of other causes which are at present unknown.

SPONTANEOUS CURE OF A SEVERE ABDOMINAL WOUND.

DR. SCHILDT mentions in *Duodecim*, a Finnish medical journal, a case, showing that, occasionally at least, a large wound into a serous cavity which looks hopeless enough may heal without treatment. He was called some years ago to a poor man supported by charity, who, in consequence of inflammation of the groin, had a large gaping wound of the abdominal wall, through which some six inches of the small intestine protruded, all covered with blood, added to which there was a discharge of fetid matter. The man was sent to the hospital, where, however, he could not be admitted, as all the beds were full. He was therefore taken home again, and received no treatment whatever. Nevertheless, Dr. Schildt a short time ago happened to see him alive and well, the wound having healed spontaneously.

MEDICAL EXPOSITION AT MILAN.

THIS undertaking may be regarded as a natural outgrowth of the Italian "Legge Sanitaria," or Public Health Act, promulgated on Dec. 22nd, 1888. That great statute, with which the name of Bertani is indissolubly connected, has given to sanitation and hygiene in Italy an impetus which increases from year to year. At the close of May and beginning of June a sanitary congress will be held in the Lombard capital to form the basis of a "Lega di Resistenza e Previdenza," in which the working practitioners and health officers of the Italian kingdom will combine for self-organisation and protection, in the first instance, and for the furtherance of the sanitary interests of the people in the second. The organising committee includes many of the most prominent names in medicine, surgery, and hygiene throughout the peninsula, and its programme, now before us, is at once comprehensive, practical, and enlightened. Concurrently with the sittings of the Congress, at which this programme will be discussed, an exposition on the largest scale of the whole armamentarium of the healing art, public as well as private, will be on view. Every implement in the armoury of the working practitioner, consultant, and health officer will be represented. Aliments of all kinds; pharmaceutical specialties, including the latest accessions to the various pharmacopœias; surgical and orthopædic apparatus; mechanical aids to diagnosis and therapeutics; plans of hospitals, civil, naval, and military; the most recent innovations in hydrological and climatic health resorts as well as in the Red Cross service in the field and afloat; statistical tables and medical publications of every category, will form the *matériel* of the exposition. Special juries of experts have been nominated to award prizes for the best examples or specimens of the above appliances, products, or plans, and Milan, the seat of Congress and Exposition alike, will

Digitized by Google

utilise her great resources for facilitating the participation of visitors at both. The recent epidemic through which she has passed—more severe in its incidence than in any other centre of Upper Italy—may be supposed to have quickened her initiative in the great prophylactic and therapeutic enterprise she has set on foot, and her example, we doubt not, will be followed in future years by other Italian cities, to the furtherance of medical science and the improvement of the health conditions, hitherto so little satisfactory, throughout the peninsula.

INSPECTION OF EXAMINATIONS BY THE GENERAL MEDICAL COUNCIL.

AS reported in the proceedings of their last session, the Council then resolved to appoint an inspector of examinations, to visit and report on the final examinations in medicine, surgery, and midwifery in the three divisions of the United Kingdom during a period of three years. We now learn that the appointment of the inspector for this year will be made by the Executive Committee at its meeting on Feb. 22nd. We presume therefore that any of our readers who may desire to become candidates for the inspectorship would do well to take such steps as they may deem desirable in the matter. The emoluments attached to the post are a salary of £200 per annum, together with travelling and hotel expenses.

"THE DOCTOR WOULD NOT COME."

MANY jurymen seem to be under an impression that medical men are paid officers of the State, and bound to go at everybody's or anybody's call. Mr. Braxton Hicks recently very properly explained to such a juryman at an inquest on the body of a child that doctors were not bound to come when called. And he added when people knew this they would be "more likely to send for a medical man when he could do a person good," instead of waiting till death was threatened. The coroner is quite right. This is not a time for medical men to stand upon their rights or to discuss abstract questions. No profession is more ready than ours with its help and its pity by night or day. But there is a limit even to medical kindness, to say nothing of the physical limits of strength and time. A little more consideration for medical men and medical service will be amply recognised by the profession. This will be shown in two ways, as the coroner suggested—in calling them in early to save life, and not merely to certify the cause of death, and in paying them promptly and with some regard for their calling.

DEATH AFTER VACCINATION.

MR. JOHN TROUTBECK has just concluded an inquest on the body of a child aged three weeks, who had been vaccinated eight days after its birth in the workhouse in the Buckingham Palace-road. The facts of the case appear from the published evidence to be as follows: The baby was an eight months child, weighing only 4 lb 3 oz. After its vaccination its mother took it out of the workhouse and applied cold cream to the child's arm, and a few days later the child died. Mr. Oliphant Langston, surgeon, of Broadway, Westminster, said that at a necropsy he found all the organs healthy, and that he had no hesitation in saying that death was accelerated by vaccination. Mr. Bond and Mr. Webb, the latter of whom vaccinated the child, said, however, that death was due to the condition of the child's lungs, Mr. Bond expressing the opinion that the presence of the sore on the arm could not fail to hasten the death of a child in such a condition. It is obvious from the evidence that the arm had not healed, and on this point Mr. Bond added that cold cream applied to the vesicles would dissolve the natural crust on the child's arm. The jury eventually returned a verdict that death was due to congestion of the lungs accelerated by the sores on the arm, but exonerated Mr. Webb from all blame. It is certain that the vaccination was done under very unfavourable conditions. The child's mother had been deserted by her husband, and in her trouble had taken refuge in the workhouse, but left shortly after the vaccination of the child, taking it with her. The mother, in her ignorance, adopted the course most likely to prevent the healing of the arm, which was very likely retarded by the lung affection from which the child suffered.

RETINAL BLOODVESSELS.

DR. JAMES MUSGROVE gives an account in the last number of the *Journal of Anatomy and Physiology* of a method of preparing the retinal vessels for demonstration either with the naked eye or with the lantern. His observations were carried out on the eye of the ox, but his method is equally applicable to that of other animals or of man. In the case of the ox the injection can be made quite well after the eye has been removed from the orbit. As much as possible of orbital fat and tissue should be removed with the eyeball, and the vessels are to be cut far back. The injection is made through the ophthalmic artery with a hand syringe, and the eye should be kept in hot water for half an hour before the injection is made. When the injection is completed the eye is allowed to cool for two or three hours to allow the gelatine in the injection to set. The entire retina is then removed by cutting through the cornea and iris and removing the lens and vitreous. The retina is then found hanging down from the optic disc, and its attachment there is divided with a knife. The entire retina may thus be freed and floated out on water, and it is then spread out, with considerable trouble it is true, on glass by means of a small camel-hair pencil. The specimen is then dehydrated and clarified in oil of cloves, after which balsam dissolved in benzol is spread over it, and another thin lantern slide used as a cover glass. In this way the retinal vessels can be clearly demonstrated, and Dr. Musgrove gives a short account of their distribution, in which he found a remarkable uniformity in the different retinæ examined.

THE DELAY AT THE VENICE CONFERENCE.

IT has been stated that the International Sanitary Conference, held at Venice, has been retarded in its work because the English delegates had to refer home for instructions the proposals made by the French delegates. This, we must confess, is a somewhat peculiar way of explaining the delay. There was nothing novel or unexpected in the French proposals which were presented to the recent International Congress of Hygiene by Dr. Brouardel, who was delegated by the French Government to discuss this matter in London. The French Government had again delegated Dr. Brouardel to repeat the same proposals at Venice. In vain we protested at the time that the International Congress of Hygiene was not meant to be a mere picnic of irresponsible sanitary reformers gathered together just to read papers and exchange ideas. We insisted that these congresses laid down the basis of future sanitary legislation. We pointed out that most of the Governments of Europe sent official representatives who were to bring back to the statesmen of their respective countries advice as to what sanitary legislation was necessary; especially is this the case with respect to all international measures for the preservation of public health. The French official delegates were therefore prepared and anxious to lay before the Congress held in London last August the very proposals which would appear to have come as such a surprise upon the conference now sitting at Venice. Dr. Brouardel, in his speech delivered in the first section (Pre-

Digitized by Google

ventive Medicine), alluded to these proposals, and he was naturally not a little surprised to find that the statements which were practically, if not officially, proposals emanating from the French Government were barely noticed and but feebly discussed. Now, after five months' lapse of time, similar proposals are made at Venice by identically the same French official delegates, and the English representatives have to refer them home for further instructions!

INTESTINAL OBSTRUCTION FROM MECKEL'S DIVERTICULUM.

ODERFELD publishes in the *Gazeta Lekarska* the particulars of an operation for acute obstruction of the bowel caused by the presence of Meckel's diverticulum. The distal end of the diverticulum had become attached to the mesentery, thus forming a loop through which a coil of intestine had slipped. The excessive formation of gas in the bowel had compressed the knuckle of intestine and caused it to become fixed. The author, in performing laparotomy, freed the incarcerated coil by separating the adherent end of the diverticulum, and to prevent a relapse he removed the latter by a circular incision at its base. The patient recovered. Oderfeld also discusses the mechanism, pathology, and the various causes of this form of obstruction, and states that no case is known in which the cause of the obstruction was diagnosed before the operation. Two symptoms, however, possess a certain diagnostic value. When obstruction occurs in a patient suffering from harelip or some other congenital deformity, the former is probably due to the presence of Meckel's diverticulum. It is also important to have the history of the patient's early life. When during the latter an umbilical fistula has existed with fæcal discharge, which, however, has occasionally healed voluntarily, the same conclusion may be drawn.

CEREBRAL LOCALISATION.

IN a recent number of the *Dublin Medical Journal* Dr. E. H. Bennett describes a case which presented an interesting condition with reference especially to the question of cerebral localisation. The patient was a man of forty-five, who was first seen by Dr. Bennett in September, 1890. At that time he had much difficulty in walking, and even in standing. His articulation was slow and indistinct, but he used correct words; his expression was vacant, his eyes prominent, and his memory much impaired. There was no definite paralysis of the limbs. His power of standing became gradually more impaired, and he was even unable to sit on a chair without falling. He fell to the right side. His memory also became worse, and his mental condition generally more feeble. There was no optic neuritis. The intensity of his symptoms gradually increased, and he passed into a comatose condition, in which he died on Dec. 3rd. Even at the last there was no definite paralysis, and his ability to move the arms and legs as he lay in bed was retained. At the necropsy it was found that there was a tumour of the brain substance, which involved the convolutions of the right hemisphere. It was hemispherical in shape, about the size of half a Tangerine orange, the flat base being directed outwards to the dura mater, which was adherent to it, and the rounded surface inwards. It lay directly over the fissure of Sylvius, obliterating the lower two-thirds of the fissure of Rolando. The lower half of the ascending parietal convolution was involved, except ten millimetres of its lower end. The whole of the ascending frontal convolution, except twenty-five millimetres above and ten millimetres below, was involved in the tumour, and no were parts of the middle and inferior frontal convolutions. It will thus be seen that a considerable part of the so-called motor area was affected by the tumour, and yet there was no definite paralysis. It is not easy to offer any explanation of such a condition, unless we are to suppose that the tumour, growing as it apparently did from the membranes, and pressing inwards on the cortex, had led to very greatly impaired function of the cortex cerebri without any actual abolition of it, and with reference to the possibility of such an explanation it would be very interesting to know the condition of fibres in the corona radiata, in the internal capsule, and in the pyramidal tracts of the cord.

DEATH OF DR. ALFRED CARPENTER.

WE regret to announce the death of Dr. Alfred Carpenter of Croydon, Surrey, at the age of sixty-eight years. He was a native of Northampton, and took a prominent part in public affairs. He was J.P. for the county of Surrey. In the year 1882 he was appointed a member of the Royal Commission appointed to inquire into the condition of small-pox hospitals, and took an active interest in all questions of social economics. As a sanitarian he occupied a very eminent position, and his ideas on preventive medicine, hygiene, and the utilisation of sewage have given rise to much inquiry, and many beneficial results have been effected through his agency. He was a strong temperance advocate.

THE ANALYSIS OF RUSSIAN BREAD.

ACCORDING to *Reuter*, the Russian papers of last Monday published the official analysis of the adulterated flour recently bought by the Municipality of St. Petersburg city. The result would appear to show that it was not adulterated to such an extent as the *Novoe Vremya* announced some days ago. While this statement appears in a negative form, yet the fact that it is qualified by the sentence "to such an extent" does obviously indicate a certain amount of adulteration. The exact details of an analysis of Russian bread carried out in our laboratory appeared in our columns last week, and the results showed an adulteration, even in this specimen which was regarded as unusually good, equal to the addition of ten pounds of foreign substances to every hundredweight of flour. Our report was read with very general interest, inasmuch as it demonstrated distinctly that the flour had been tampered with, not, perhaps, to an excessive extent, as has been believed, but still to an extent which is both unpardonable and unjustifiable. In respect to the results, it is so far satisfactory to learn that our report is practically confirmed by the Russian official analysis, although the *Novoe Vremya* maintains that the official analysis is misleading, and it cites the opinion of several experts in support of this contention.

CASE OF URETHRO-VAGINAL FISTULA OPERATED ON BY VAGINAL FLAP.

Dr. OKER-BLOM relates the case of a farmer's wife who had lost the greater part of her urethra in her first confinement. The whole of the middle portion extending backwards as far as the bladder had been destroyed, whilst of the anterior portion only 1 centimetre remained. The sphincter itself was injured. The tissues between the neck of the bladder and the symphysis had disappeared, a cavity occupying their place. The entrance to the bladder below and behind was blocked by the vagina. The orifice of the vagina was narrow and extremely rigid, the mucous membrane being replaced by cicatricial tissue, which extended from side to side. The following operation was performed. In the first place the edges of the opening into the bladder, and of the remains of the urethra, with the tissue between them beneath the symphysis, were freshened, then the edges of the opening into the bladder were sutured to the remains of the urethra, the portion nearest the symphysis requiring four good-sized catgut sutures. The cavity beneath the symphysis closed by first intention, but the strain being too great, the stitches gave way. To

Digitized by Google

remedy this, a flap of mucous membrane was raised from the right side of the vagina. The posterior edge of this flap was sutured to the opening into the bladder, and the anterior edge to the remains of the urethra, whilst the middle portion was united to the tissues on the left below the symphysis. In this way a new urethra was formed, which healed by first intention. As no sphincter existed, a plug of cork was used as a substitute, which the patient always carried with her, and which closed the channel into the bladder sufficiently to prevent the escape of urine, but at the same time did not prevent micturition. She has for a month been able to follow her occupation in the fields without suffering the slightest inconvenience arising from the bladder.

RETRO-UTERINE HÆMATOCELE.

THE *Pester Medicinisch-Chirurgische Presse* reports a lecture by Dr. H. Swiecicki of Posen before the medical association of that city in which he discusses the various sources from which retro-uterine hæmatocele may originate, such as the Fallopian tubes, ovaries, and uterus, and mentions the immediate causes of the affection. He considers adhesions, followed by bleeding from beneath, as necessary factors in producing the hæmatocele, and mentions extra-uterine pregnancy as the most usual predisposing cause. He discusses the formation and course of the various kinds of the latter, and its relation to pelvic hæmatocele, and expresses it as his opinion that gonorrhœa and previous perimetritis are the most frequent causes of the abnormal pregnancy. Retro-uterine hæmatocele cannot be produced artificially, so that it appears other causes are present for the formation of the tumour besides adhesions and bleeding. Swiecicki agrees with Veit that the blood in the peritoneal cavity may coagulate, though slowly, and that the coagulum adheres easily to the pseudo-membranes. This process goes on until, by the continually increasing collection, pressure is exercised on the bleeding vessels, and may arrest further oozing. This bleeding is apt to take place in the direction in which the tissues are least capable of resistance—that is, towards Douglas' pouch. The treatment may be either expectant or operative. The latter consists in puncture per vaginam or per rectum, or in incision per vaginam or laparotomy. Swiecicki favours an expectant and symptomatic treatment, and, if operating at all, would either incise per vaginam or perform laparotomy. He considers the operation indicated when the hæmatocele is of considerable size, when the tumour shows no symptom of absorption after several weeks' expectant treatment, when septicæmia or pyæmia has begun, or when excessive pains or other unfavourable symptoms affecting the bladder or rectum exist.

INTESTINAL OBSTRUCTION DUE TO A LARGE GALL-STONE.

AN interesting example of this rare form of obstruction of the intestines occurred in a patient who was recently submitted to abdominal section and a large gall-stone removed. The patient, a man aged forty-three, consulted Dr. Murphy of West Malvern, on Dec. 20th, 1891, for a supposed bilious attack. He had been vomiting for three days, and there had been no action of the bowels for two days. The vomited matter was copious, and contained a large quantity of bile. There was great thirst, but no pain. Some resistance could be felt in the abdomen to the right of the umbilicus. Very little improvement followed the treatment commenced at that date, and on the 25th Dr. Brockatt of Great Malvern saw the patient in consultation and advised operation. This was performed early on the following morning. Under an anæsthetic, a hard, movable lump could be felt in the right iliac region. After opening the abdomen, this lump was found to be a hard mass which completely blocked the lumen of the small intestine. The intestine was held by the fingers above and below the obstruction, and an incision made in the long axis of the intestine, and what proved to be a large gall-stone was extracted. The intestine near was washed out thoroughly and the wound closed with Lembert's sutures. The patient had no further abdominal symptoms, but sank and died from exhaustion on the 31st of last month. Only a partial examination of the abdomen was permitted by the friends. There was slight peritonitis of some of the superficial coils of intestine on the right side in the neighbourhood of the wound, which was itself firmly united, and situated high up in the jejunum. On tracing the small intestine upwards, it was found to be firmly matted together by old adhesions, and the gall-bladder was incorporated with the mass and could not be separated. The gall-stone was unusually large, was pear-shaped, and measured 2 in. in length, 1¾ in. in its greatest transverse diameter, and 5½ in. in greatest circumference. In February of last year the patient was seen by Dr. Murphy for an attack of acute pain in the abdomen, which lasted for twenty-four hours, but was unattended by vomiting or followed by jaundice. His occupation was sedentary; but, with the exception of this attack, his health had been good.

FOREIGN UNIVERSITY INTELLIGENCE.

Berlin.—The next "vacation course" of lectures and demonstrations will commence on March 9th, and will continue until April 6th. An elaborate prospectus has just been published.

Breslau.—Professor Kast of Hamburg has been appointed Professor of Clinical Medicine in succession to Dr. Biermer, resigned.

Gratz.—Professor Kratter of Innsbruck has been appointed to the chair of Forensic Medicine.

Kharkoff.—Dr. Openkhovski of St. Petersburg has been appointed Extraordinary Professor of Therapeutics.

Strasburg.—Dr. Ernst Mehnert, Assistant in the Anatomical Institute, has been recognised as *privat docent* in Human and Comparative Anatomy with Embryology.—Dr. Martin Schmidt, Assistant in the Pathological Institute, has been recognised as *privat-docent* in General Pathology and Morbid Anatomy.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.

THE deaths of the following distinguished members of the medical profession abroad have been announced:—Dr. A. Casini, Lecturer in Surgery in the University of Naples.—Dr. Palmer, formerly Professor of Physiology in the Howard University, Washington.—Professor Weber-Liel, of Bonn.

AT the annual meeting of the Obstetrical Society of London, on Wednesday, Feb. 3rd, there will be a ballot for the election of Sir Joseph Lister, Bart., and Sir William Turner, as honorary Fellows (British subjects), and for the election of Professor Credé and Dr. Lusk as honorary Fellows (foreign subjects). The number of British honorary Fellows is limited to six, and foreign honorary Fellows to ten.

THE death is announced of Dr. Leighton, the father of the President of the Royal Academy. The deceased physician was ninety-three years of age, and some years ago retired, after having enjoyed a long practice in Scarborough.

WE understand that at the third Lettsomian lecture on Monday next Mr. Rose will demonstrate on the dead subject the steps of his operation for removal of the Gasserian ganglion.

WELLINGTON COLLEGE SORE-THROAT.

BY J. G. BARFORD.

(*Continued from page 159.*)

"THE bleak, inhospitable moor on which the building has unfortunately been erected wore for the first time such a busy aspect as was almost sufficient to give an air of animation to a spot so desolate and cold" is the opening paragraph of *The Times'* leading article on the inauguration of the public opening of this institution by Her Majesty thirty-two years ago. The article goes on to state that, short as the distance is from the station to the College, it was "quite sufficient to enable all to appreciate the bleakness of the situation, for wind and drizzling rain were sweeping across the heath with vindictive keenness, and altogether the appearance of things was as cheerless and unpromising as well could be." Prior to the opening day the five or six masters assembled and some sixty boys, having found their way to the College with difficulty, for there were no roads completed, and much of the land was a perfect slough. The season was a wet one, and the building very incomplete. Under these conditions I was appointed to undertake the medical charge of the institution. A few days before the boys assembled I went over to the place on a tour of inspection, and met the present Archbishop of Canterbury, who had been appointed head master. We made each other's acquaintance, the one not knowing in the least who the other was till we announced our respective names. The look of things was not encouraging; but we got over the first term without any very alarming illness. Some cases of pneumonia and bronchitis were our chief sources of anxiety, and a distinctly malarial form of "recurrent febricula" cropped up, and in this as in subsequent terms for years was very prevalent, accompanied by the peculiar form of progressively developing sore-throat, in its mild and benign form as a rule, but occasionally in its malignant form, and this has been a feature at Wellington College from the time the building was first tenanted, in 1859, to 1891, when it appears to have reached its most virulent phase, necessitating the dispersal of the school for part of one term and the whole of another. To trace the slow, but surely progressive, nature of the affection it is necessary to recognise its association with the peculiar forms of recurrent feverishness to which the boys were liable from the commencement of the College, and which also affected the able-bodied convicts who were sent to Broadmoor Asylum to labour at the trenching and other earth-works which had to be done before the asylum was fit for the lunatic inmates. These able-bodied convicts I had the charge of, and thus was afforded an opportunity of comparing their maladies with those at Wellington College.

The recurrent feverish attacks to which the boys and convicts were both liable were of a distinct malarial type. The sparse population of the district anterior to the appearance of Wellington College and Broadmoor Asylum consisted of a peculiar race of hardy natives who became celebrated in Kingsley's works, and were known as broom-dashers, as their sole occupation was making heath brooms, which in the process of construction are dashed against a block of wood to give them shape and firmness; hence, I presume, the name "broom-dasher" arose. They were a peculiar, uncultivated race of the gipsy type. They lived in huts made of turf, with no flooring but the bare ground. Ague was common among them, as indeed it was all around this district and the adjacent portion of Hampshire.

But Dr. Bristowe, in his report to the Governors of Wellington College, states that there is no malaria. He can know but little about the disease tendencies of the locality. He states in his report to the Governors that "the term malarious as applied to the district is wholly inaccurate and misleading." If Dr. Bristowe would do me the favour to pay me a visit I would take him to see a patient who had distinct ague, and he shall hear it from the patient himself and listen to an accurate description of an ague fit. When the South-Eastern Railway was being constructed through the portion of the country where Wellington College now stands the navvies suffered very much from ague. *The Times* article above referred to states that Wellington College "faces immediately" on Hampshire, and Hampshire is known to have been distinctly malarious, and is one of the few counties named as indubitably so. Dr. Bristowe, in his article on Malaria, draws largely from Sir Thomas Watson's lectures. Watson states that malaria may be present one month in a locality and absent the next; yet Dr. Bristowe, from a few visits in one month of the year, and the least likely month for malaria to display itself, draws his sweeping conclusion that there is no malaria in the locality. James I. and Oliver Cromwell both died of ague contracted in London, and it is no more disparagement to Wellington College to say that ague occurred than it is to London to say it was once very malarial, and that still in London as at Wellington College a distinct malarial taint can be traced in some cases of acute disease playing through the other symptoms as distinctly as the treble in a chorus. So long as the authorities of Wellington College shut their eyes to these facts, so long will they fail to realise the true nature of much of the illness there, and to this error Dr. Bristowe lends his name and authority. There is a distinct association between the malarial disposition and the Wellington College sore-throat, and the malignant septicæmia which has occurred there in excess of any other locality of the same population in the country, which I will hereafter point out more in detail.

(*To be continued.*)

THE INFLUENZA.

So far as can be gleaned from the reports in the daily press, there is no appreciable abatement in the epidemic of influenza, for although the disease is leaving some districts it is still spreading in other parts of the country. In the metropolis there is no question as to the great prevalence of the malady; but none of the hospitals seem to be so overwhelmed with cases as they were during the first week of 1890. However, there is much sickness from bronchitis and pneumonia, of which several cases must be attributed to an antecedent attack of influenza, without any correspondence in severity between the primary illness and its sequel. The Registrar-General's returns for the week ending Jan. 23rd show, as regards mortality, a great increase in the deaths primarily attributed to influenza in London—viz., 506—the number for the previous week being 271; and in addition there were 86 cases in which influenza was returned as a secondary cause. The latter figure is of course only approximate, for it appears that the deaths referred to diseases of the respiratory organs rose to 1465, or 868 in excess of the corrected average. Turning to the general death-rates of the large towns of England and Wales, it is remarkable to find the list headed by a town which in its annual rate is very near the other end of the scale. This is Brighton, where the death-rate last week was as high as 60·9 per 1000. In mitigation of this exceptional mortality, which can only be ascribed to influenza and its complications, it must be observed that this town is the nearest health resort to London, and has doubtless received more invalids than customary this winter. Dr. Newsholme, the medical officer of health for Brighton, has prepared a special report on influenza, which describes in a succinct and readable manner what is known concerning its nature and mode of propagation, with timely suggestions as to precautionary measures to be taken in households where cases may arise. Dr. Newsholme, speaking of the high rate of mortality, due, in his opinion, chiefly to the excessive mortality among aged and invalids from the sequelæ of influenza and other causes, draws especial attention to the risk of drawing false inferences from noting only one week's returns. But it may be remarked that the average death-rate for Brighton during the past four weeks has been no less than 46·9, whilst London (which last week had a mortality of 46) gives an average for the same period of 40·2. Influenza is said by the medical men at Brighton to be declining, and the present high death-rates are largely due to the attacks of

Digitized by Google

previous weeks. There has been a decline in the rate at Portsmouth, which was 44·3 last week; but Norwich has advanced from 40·1 to 44·7. The lowest rates were in Huddersfield, 17·3; Leicester, 19·1; Nottingham, 19·4.

In the Home Counties influenza is still very prevalent, especially in Essex and North Kent; and in Berkshire, Herts, and Bedfordshire fresh cases continue to occur.

Dr. Thresh, medical officer of health of the Chelmsford rural sanitary district, writes:—"In both the rural and urban districts this disease is very prevalent and of a severe type. In the Chelmsford rural district three schools have had to be closed for lack of scholars. The death-rate for this district during the past three weeks has been at the rate of over 50 per 1000. More deaths from influenza have occurred this month, so far, than during the whole of last year. The majority of those who succumb are over sixty-five years of age. The epidemic is extending in all the districts." Dr. Thresh has issued a special report, and advises exactly the same precautions to be taken with patients suffering from influenza as would be taken if they were known to be suffering from scarlet fever.

On the whole, it seems to be less prevalent in Dorset and Hants, but only this week has it appeared in North Somerset, although it has been longer prevalent in other parts of the county. Thus a medical man at Martock writes:—"Influenza is rampant. . . The cases this year in our neighbourhood are, as a rule, very severe, and relapses are very common, whilst, as complications, pneumonia of an insidious type is often met with. Bronchitis is very frequent, especially among old people. More common than pneumonia, and about as frequent as bronchitis, is gastro-enteric disturbance of a more or less severe character. . . . In some cases the abdominal pain and diarrhœa are extreme."

In Leicester we are informed that "influenza still remains comparatively mild, and does not extend with any great rapidity. No deaths were recorded last week, and the deaths from respiratory diseases, as well as the general mortality, remain unusually low." Less reassuring statements come from Northampton, where it has recently broken out, although for some time it has been prevalent in the district. In Huntingdonshire and Cambridgeshire, as well as in Norfolk and Suffolk, there does not seem to be any appreciable abatement. The epidemic is spreading in Lincolnshire and in the North Riding of Yorkshire. It is also on the increase in Liverpool.

On the Continent influenza is still prevalent in Paris and the South of France, notably Lyons; but it is abating in the northern departments. It is also subsiding in Italy, and has almost ceased at Malta and in most parts of Germany, although it is still very severe at Mecklenburg. There is a decrease in its virulence in Copenhagen, but it has appeared with considerable severity at Christiania, Bergen, and other parts of Norway. It has once more appeared at St. Petersburg, and is very severe in Odessa and South Russia generally.

A piece of intelligence which we are not able to confirm comes from Berlin, in the letter of the *Standard's* correspondent (Jan. 20th)—viz., that an International Influenza Conference is to be held in London in March, with Sir W. Jenner as president. The number of deaths in Berlin from influenza, not counting its sequelæ, from the beginning of last November till the New Year was 411. Eight of the fifteen normal schools in Saxony are closed owing to influenza. The number of cases officially determined in Vienna from the 3rd to the 9th inst. was 521. Dr. Ripperger of Munich has published a book entitled "The Influenza, its History, Epidemiology, Etiology, Symptomatology, Treatment, Complications, and Sequelæ." It gives an account of all the influenza epidemics on record since 1387. The number of references is over 3000.

As to other parts of the world, there is still much sickness from this cause in the United States, and this week has brought information of an outbreak at Cape Town.

YELLOW FEVER ON A MAIL STEAMER.—Messrs. Shaw, Savill, and Albion Company's steamer *Arawa* arrived at Plymouth on the 21st inst. Owing to yellow fever having broken out on board after leaving Rio on the 3rd, the vessel will be detained in quarantine, and has been ordered to proceed to the Mother Bank under yellow fever signals. The mails were fumigated and forwarded to London by special train.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

St. George, Hanover-square.—The corrected death-rate for this parish during 1890 was 14·56 per 1000 of the inhabitants; but Dr. Corfield does not accept the official census, because it was made to depend on a Sunday night, when many of the inhabitants are always away, and because of the Easter holidays, which also largely interfered with the residence or not of many of the parishioners in their own homes. During the last sixteen years the mean length of life has averaged nearly 54 years in this parish; it has also gradually increased, and for 1890 it is set down at 62·67 years. The zymotic rate was 1·6 per 1000. The report, which is mainly statistical, concludes with an account of the general sanitary work of the year.

Ampthill Parish.—Dr. J. H. Garrett presents a special report on this parish, as to which he gives a very complete account, beginning with its topography, geology, &c., and containing a detailed description of all the prevailing sanitary circumstances. Evidently the place stands in need of much sanitary reform: its sewerage is very faulty, the closet accommodation is most unsatisfactory, and a public water-supply is urgently required. Ampthill possesses certain very marked advantages of site and soil; and it is much to be hoped that the careful report compiled as to its advantages and its many wants will induce the sanitary authority to do their duty towards the parish, and free the place from all those conditions which tend to unhealthiness. What that sanitary authority is to be remains to be seen, for opposition has been raised as to the constitution of a local board district. Dr. Garrett's report shows that the wants of Ampthill are essentially local ones, and the place seems certainly to be sufficiently compact to justify the formation of a local body that will have more interest in its sanitary circumstances than has been shown, since the passing of the Public Health Act (1875), by the guardians, who are scattered all over the union, and have other things to think about than the wants of this special parish.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6328 births and 6884 deaths were registered during the week ending Jan. 23rd. The annual rate of mortality in these towns, which had been 28·7 and 33·0 per 1000 in the preceding two weeks, further rose last week to 35·4. In London the rate was as high as 46·0 per 1000, while it averaged only 27·6 in the twenty-seven provincial towns. The lowest rates in these towns last week were 17·3 in Huddersfield, 19·1 in Hull and in Leicester, 19·4 in Nottingham, and 19·8 in Halifax; the highest rates were 40·0 in Liverpool, 44·3 in Portsmouth, 44·7 in Norwich, 46·0 in London, and 60·9 in Brighton. The 6884 deaths included 518 which were referred to the principal zymotic diseases, against 549 and 604 in the preceding two weeks; of these, 254 resulted from whooping-cough, 124 from measles, 41 from diarrhœa, 38 from diphtheria, 32 from scarlet fever, 26 from "fever" (principally enteric), and 3 from small-pox. No fatal case of any of these diseases was registered in Halifax, while they caused the lowest rates in Portsmouth, Plymouth, and Gateshead, and the highest rates in London, Derby, Liverpool, and Swansea. The greatest mortality from measles occurred in Derby, Liverpool, and Swansea; from scarlet fever in Swansea; from whooping-cough in Wolverhampton, Brighton, Bolton, Oldham, London, Blackburn, and Derby; and from "fever" in Salford. The 38 deaths from diphtheria included 23 in London, 2 in Croydon, 2 in Norwich, and 2 in Newcastle-upon-Tyne. Three fatal cases of small-pox were registered in Liverpool, but not one in London or in any other of the thirty-three great towns; 6 small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and 2 in the Highgate Small-pox Hospital. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London

Digitized by Google

Fever Hospital at the end of the week was 1397, against numbers declining from 1554 to 1391 at the end of the preceding seven weeks; 116 new cases were admitted during the week, against 104 and 92 in the previous two weeks. The deaths referred to diseases of the respiratory organs in London, which had been 1084 and 1248 in the preceding two weeks, further rose last week to 1465, and exceeded by as many as 868 the corrected average. The causes of 111, or 1·6 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Bolton, Oldham, Newcastle-upon-Tyne, and in four other smaller towns; the largest proportions of uncertified deaths were registered in West Ham, Swansea, Sheffield, and Liverpool.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had declined in the preceding four weeks from 27·1 to 23·9 per 1000, rose again to 27·2 during the week ending Jan. 23rd, but was as much as 8·2 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 21·8 in Edinburgh and 23·7 in Paisley to 29·7 in Greenock and 31·9 in Dundee. The 756 deaths in these towns included 24 which were referred to whooping-cough, 13 to diarrhœa, 11 to measles, 10 to scarlet fever, 9 to diphtheria, 5 to "fever," and not one to small-pox. In all, 72 deaths resulted from these principal zymotic diseases, against 58 and 50 in the preceding two weeks. These 72 deaths were equal to an annual rate of 2·6 per 1000, which was slightly below the mean rate last week from the same diseases in the thirty-three English towns. The fatal cases of whooping-cough, which had been 22 and 16 in the preceding two weeks, rose again last week to 24, of which 10 occurred in Glasgow, 5 in Aberdeen, and 4 in Paisley. The 13 deaths from diarrhœa showed a slight further increase upon recent weekly numbers, and included 9 in Glasgow. The 11 fatal cases of measles exceeded by 7 the number in the previous week; 9 occurred in Glasgow and 2 in Edinburgh. The deaths from scarlet fever, which had been 4 and 7 in the preceding two weeks, further rose to 10 last week, of which 8 occurred in Glasgow. The 9 fatal cases of diphtheria showed an increase of 4 upon the number in the previous week, and included 4 in Glasgow and 3 in Aberdeen. The 5 deaths from "fever" were below those recorded in any recent week. The deaths referred to diseases of the respiratory organs in these towns, which had been 200 and 226 in the preceding two weeks, were 230 last week, and exceeded by 20 the number in the corresponding week of last year. The causes of 53, or more than 7 per cent., of the deaths in the eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 35·0 and 43·8 per 1000 in the preceding two weeks, further rose to 54·1 during the week ending Jan. 23rd. During the first three weeks of the current quarter the death-rate in the city has averaged 44·3 per 1000, against 39·6 in London and 22·1 in Edinburgh. The 363 deaths in Dublin during the week under notice exceeded by 69 the number in the preceding week, and included 10 which were referred to whooping-cough, 5 to "fever," 2 to diphtheria, 2 to diarrhœa, 1 to measles, and not one either to small-pox or scarlet fever. In all, 20 deaths resulted from these principal zymotic diseases, equal to an annual rate of 3·0 per 1000, the rate during the same period being 3·7 in London and 1·8 in Edinburgh. The fatal cases of whooping-cough, which had been 10 and 5 in the preceding two weeks, rose again to 10 last week. The deaths referred to different forms of "fever" (principally enteric), which had been 5 and 2 in the previous two weeks, rose again to 5 last week. The two fatal cases of diphtheria exceeded the number recorded in any week since September last. The 2 deaths from diarrhœa were within one of the number in the preceding week. The 363 deaths registered in Dublin last week included 47 of infants under one year of age, and 147 of persons aged upwards of sixty years; the deaths of infants showed a slight decline, while those of elderly persons showed a marked further increase upon recent weekly numbers. Three inquest cases and one death from violence were registered; and 163, or nearly one-half, of the deaths occurred in public institutions. The causes of 24, or nearly 7 per cent., of the deaths in the city were not certified.

THE SERVICES.

Surgeon-Lieutenant-Colonel J. G. Rogers, M.B., D.S.O., has vacated his appointment in the Egyptian Army.

ARMY MEDICAL STAFF.—The surname of Surgeon-Major-General D. A. C. Fraser, M.D., placed on retired pay in the *Gazette* of Jan. 12th, 1892, is as now, and not as therein stated; Surgeon-Colonel Alfred M. Tippetts to be Surgeon-Major-General, vice D. A. C. Fraser, M.D., retired, and Brigade Surgeon-Lieutenant-Colonel William C. Robinson to be Surgeon-Colonel, vice A. M. Tippetts (both dated Dec. 27th, 1891); Surgeon-Lieutenant-Colonel William McWatters to be Brigade Surgeon-Lieutenant-Colonel, vice S. E. Maunsell, deceased (dated Dec. 16th, 1891); Surgeon-Lieutenant-Colonel Robert N. Mally to be Brigade Surgeon-Lieutenant-Colonel, vice W. C. Robinson (dated Dec. 27th, 1891); Surgeon-Captain John Lees Hall, from half pay, to be Surgeon-Captain, vice T. F. W. Fogarty, M.B., deceased (dated Jan. 3rd, 1892).

ARMY MEDICAL RESERVE OF OFFICERS.—The Queen has been graciously pleased to approve of the following alterations of designation in the rank of Officers of the Army Medical Reserve of Officers (dated Jan. 1st, 1892):—Surgeons-Major (ranking as Lieutenant-Colonels) to be Surgeon-Lieutenant-Colonels; Surgeons-Major (ranking as Majors) to be Surgeon-Majors; Surgeons (ranking as Captains) to be Surgeon-Captains.

INDIAN MEDICAL SERVICE.—*Madras:* Surgeon-Colonel T. N. Hoysted, Administrative Medical Officer, Sirhind District, Bengal, succeeds Sir James Hanbury as Principal Medical Officer of the forces in the Madras Presidency.

NAVAL MEDICAL SERVICE.—The following appointments have been made at the Admiralty:—Surgeons: Robert Hardie, M.B., to the *Cossack*, Edward Cuffey, M.B., to the *Pigeon*, and John A. Robinson, M.B., to the *Starling* (dated Jan. 29th, 1891).

VOLUNTEER CORPS.—*Artillery:* 1st Midlothian: Lieutenant William Thomas Crawford, M.B., is appointed Surgeon-Lieutenant (dated Jan. 23rd, 1892).

Correspondence.

"Audi alteram partem."

THE INFLUENZA.

To the Editors of THE LANCET.

SIRS,—Amongst the vagaries of influenza perhaps no complications are more puzzling, and at times give more anxiety to the practitioner, than the exanthematous forms which have been observed in this and other epidemics. Rashes quite typical of scarlet fever or measles have been frequently reported. My neighbour, Mr. Ward, medical officer of health for Harrogate, tells me that he has attended at least six cases simulating scarlatina so closely as to give him anxiety in the early stages until he was able to exclude all but influenza as a cause.

A case which I am still attending shows clearly that a rash, having all the outward appearances of measles, may occur in the course of influenza. The patient, a young married lady, sent for me on the 18th inst., complaining of diarrhœa and sickness, together with pains all over the body, but chiefly on the left side of the chest. There was no temperature and no rash. The pains had been present, more or less, for five days previously. Next day I was surprised to find the patient's face and neck flushed, swollen, and covered by a roseolar, measly rash, which also extended over the chest, arms, and body. Still no temperature. A saline aperient was administered in order to help the elimination of poison from the blood. By the following day the rash had considerably faded, and the face and neck were much less swollen. Now, since the 20th inst. the rash has practi-

Digitized by Google

cally disappeared, excepting on the left side of the chest. Here a recrudescence has taken place limited to an area bounded by a vertical line drawn posterior to the axilla behind, a little to the left of the sternum in front, and from about the third to the eighth ribs. The so-called rheumatic pains, though at first general, have now concentrated themselves to the space above described, but have increased in severity so as to be spasmodic in agony. A nerve storm appears to come on with regularity every evening and early part of the night. One cannot help of course being strongly reminded of "herpes zoster," though the papular stage only has been reached, and there is no sign of vesicles forming. "Herpes zoster" itself has been mentioned among the sequelæ of influenza. My patient is of hysterical, neurotic type, and the menses are very irregular, so that neuralgic affections are not uncommon with her.

Another complication of influenza to which I scarcely think sufficient attention has been directed is "infection of the endocardium." I have seen four cases. Perhaps the prevailing symptom in all was a pretty high temperature—say, 101° to 103°—tending to be maintained for several days, and to relapse unless antipyretics were steadily given. Catarrhal symptoms were also present, but not pronounced. No complaint of pain over the precordial region was specially noticed, but faintness, as if for want of food, was observed. This, and a sort of suspicion that the case was not progressing as well as it ought, made me examine the heart, when a soft murmur with the first sound was usually heard about mid-sternum and towards the apex; in one case over the second left cartilage. The first patient in which I observed this condition of heart during an attack of influenza was an active, athletic young man. I was very much disappointed at finding the valvular trouble (thinking it was old and rheumatic), and gave a rather gloomy opinion as to the probability of his entirely recovering from it. However, I was agreeably astonished to discover that the heart had completely righted itself in about a month after the attack. In the other three cases I found that the time required was about three weeks, and I boldly predicted the return to health in the last two! During the valvular implication it would seem quite impossible to distinguish influenza from rheumatic fever by any examination of the heart. It would be a great comfort to one, therefore, to know if other observers can corroborate my own experience, that the endocarditis of influenza is erythematous and evanescent as compared with the plastic and more permanent mischief of rheumatic fever. In view of the recent discovery of a microbe which is specific to influenza, it is interesting and instructive to compare the miasmatic theory of Sir D. Maclagan as a cause of rheumatic fever, and which led to the introduction of the famous salicine treatment. Many observers, myself included, have found salicine and its compounds equally efficient in the struggle against influenza. In controlling the fever of the latter it is evidently necessary, not only that one should use an antiseptic form of antipyretic (e.g., salicine, antipyrin, phenacetin), but that the drug should be continued in its full dose, but less frequently, for a few days until the temperature has become steadily normal. Relapses are more frequent, or complete convalescence is retarded, where this plan is not carried out. Judging from several points of analogy which may be noted between measles, scarlatina, rheumatic fever, and influenza, it seems probable that their microbes come at least from the same genus, if not the identical species or family. Might not any differences in form of such microbes which belong to one genus help us to understand why some of our specific remedies are more adapted than others to meet the several requirements—e.g., fever, pain, sickness, and diarrhœa, or catarrhal symptoms? For the latter, for instance, I have found antiseptic balsams, such as guaiacum, benzoin, and tolu, made into an emulsion with tragacanth, of immense service. The addition, in some cases, of ipecacuanha wine or, in gouty congestion, of colchicum wine has also proved most helpful. Herpes zoster itself has been thought by some observers, such as Dr. Byrom Bramwell, to be of microbic origin, though I am not aware that the individual has been discovered. The pains of this affection, and its allies of influenzal type, are so intense and persistent that one would be glad to have a remedy certain to quell and cure it without having recourse to opium.

In connexion with the exanthematous forms of influenza I was struck with a statement made by my friend, Dr. H. E. Armstrong, medical officer of health for Newcastle-on-Tyne, a few days ago. He said that during the last quarter of 1891 the mortality of "measles" had been eight times greater than that of "scarlet fever." This does not seem to be in accord with one's general idea of the comparative gravity of these affections. It occurs therefore to me to ask whether cases are not being returned as measles which are in reality influenza *with a rash*? Parents are often very careless in regard to children with measles, allowing them to run about out of doors as if nothing were the matter. Under such circumstances influenza with a rash like measles would be very likely to run into fatal complications.

I am, Sirs, yours faithfully,

J. GORDON-BLACK, M.D.Lond.

Harrogate, Jan. 26th, 1892.

To the Editors of THE LANCET.

SIRS,—One of the most distressing and one of the most persistent symptoms present in the cases of influenza at present prevalent has been the occurrence of severe cough. This I have frequently observed to be out of all proportion to the amount of bronchitis present and to have remained to harass the patient's rest when the physical signs in the lungs had entirely disappeared. These facts, along with its paroxysmal nature, must have suggested to many the analogies between the condition and that of whooping-cough, which of late years has more and more come to be recognised as due to some nervous lesion. Seeing the very striking effects which the cause of influenza has upon the nervous system, is it unreasonable to suppose that the cough may be of nervous origin? A case which I have had under my care still further confirms this idea, and presents, I think, a therapeutic suggestion. In a lady recovering from influenza and suffering from this paroxysmal cough, a hernia which had formerly been reducible showed signs of strangulation, and required an operation, which was performed under chloroform as the anæsthetic. The patient made an excellent recovery, and never during convalescence again suffered from her former distressing symptoms—in fact, rarely coughed at all. Now, while I do not think it would be justifiable to chloroform every patient thus suffering, still, action along the same lines may be taken, and I have tried with good effect an inhalation consisting of one drachm of chloroform, two drachms of oil of cinnamon, and three ounces of rectified spirits of wine—a little to be occasionally put on blotting-paper, placed beneath the chin of the patient, who is enjoined to breathe quietly. The small quantity of chloroform which can be present in any inhalation suggests that it acts by soothing the terminations of the vagi in the bronchial passages, and not by any general influence.

I am, Sirs, yours truly,

Oxford, Jan. 25th, 1892. H. P. SYMONDS.

To the Editors of THE LANCET.

SIRS,—Now that the influenza is raging everywhere, and every practitioner is engaged in battling with it, I thought that some of the observations I made during the epidemic of 1890 as compared with those of the present year might be of use. During the epidemic of 1890 I was acting temporarily as superintendent in a large London infirmary, where the number of patients averaged 520, and when during the three months of December, January, and February, if I remember rightly, about 200 cases occurred either amongst the patients already in the building or who were admitted suffering from the disease and were placed in the general wards, no attempt being made at isolation.

The first point one notices between the attacks occurring then and now is that in the former gastric catarrh accompanied with persistent vomiting for the first twenty-four hours was very common, and that bronchial catarrh, if present, was slight and evanescent; whereas now in the great majority of cases bronchitis of more or less severity is present and persists for some time, with considerable elevation of temperature. In addition a few of the present cases show gastro-intestinal catarrh with profuse diarrhœa and jaundice. Observations in the previous epidemic showed that the majority of patients were young adults (from twenty to forty), neither the very young nor the old being affected in anything like the same proportion, although the bulk of the patients in the building were elderly people suffering from chronic

Digitized by Google

chest complaints, a very small proportion of whom were attacked; this being rather against the idea that disease of the respiratory organs renders the patient more susceptible to the disease. Patients who were far gone in phthisis, too, seemed to escape the disease, possibly because the high temperatures they had rendered the soil unsuitable to the microbe of influenza. In very few cases indeed did pneumonia supervene, and very few cases succumbed. Amongst the children a few cases occurred; but then, as at the present time, they had few complications, the attack consisting in a sudden onset of giddiness, high temperature, vomiting for a few hours, and bad headache, the usual complaints of general aching and severe pain in the lumbar region being wanting. Usually the temperature began to fall within thirty hours, and was normal by the third day, and was not followed by anything like the same amount of depression as amongst the adults. As to sex, we found they were affected in nearly equal numbers, females slightly predominating.

In the earlier cases the temperatures rarely exceeded 103°, but later cases always reached 104°, and many 105°, or over. The infectious nature of the disease was shown by the large number of nurses who fell victims, those having anything to do about the patients being attacked, whereas patients sleeping in adjoining beds remained free. I can only remember one case where a patient was affected in the next bed, although from its infectious nature we might have expected to see it progress round the ward from bed to bed; and its not doing so must be attributed to good ventilation and an ample cubic space per patient. This explains, too, why isolated cases occurred in wards containing thirty-two beds, none of the other patients contracting it, so that the poison seems to be like that of typhus fever, easily rendered innocuous by dilution. As regards the incubation period, I have lately had a case in private where A was taken ill, and precisely six days later B fell a victim, this patient having two children sleeping in the room with her, neither of whom had had any communication with A, and were not even allowed on the same floor, both of whom were attacked twenty-four hours after B's symptoms began. This coincides with observations reported in Dr. Sisley's book; and inasmuch as the children had been confined to the house, their source of infection seems clear. That we should isolate every case at once, as in any of the other infective diseases, is imperative; and if we can remove our patients to a top floor, and use a carbolised sheet over the door, it seems most desirable to do so. Then the question arises, How long after convalescence is the patient infectious, this being a question that is put to us daily, and which no authority to which I have access gives any clue? It seems safe to conclude that as long as any cough lasts the infection continues; but this is an unsatisfactory guide, for a patient may keep his cough for three or four weeks, and will certainly not submit to quarantine for that period. Are we safe in setting an arbitrary limit of from ten to fourteen days? After convalescence it seems desirable to disinfect the rooms; and this may be done rapidly by vaporising cresolene or by having the windows opened for two or three days, and the bedding &c. well aired.

Another question arises as to whether the disease can be conveyed by a third person who is not himself suffering from the disease. Doubtless, if the third person carries away on his dress mucous or nasal discharges, as in the case of whooping-cough, it can be conveyed, but otherwise there seems to be little danger. It is to guard against this possibility that at some of the infirmaries these patients are isolated at once and have special nurses provided, who are not allowed to mix with the others or attend in the general wards; and the results of this care will be watched with interest by all practitioners, who are naturally interested in staying the present plague and acting in the best interests of their patients.

I am, Sirs, yours truly,

RAINSFORD F. GILL, M.D. Lond.

Adelaide-road, N.W., Jan. 25th, 1892.

To the Editors of THE LANCET.

SIRS,—During this epidemic I have used nothing else but bicarbonate of potash, giving it, as recommended by Mr. Crerar, in half-drachm doses in milk every three hours, as long as the fever lasted. Last epidemic I gave salicylate of soda with bromide of ammonium after an injection of apomorphia or an aperient, and the bicarbonate treatment I find by far the best. I would not go so far as to say, with Mr. Crerar, that it destroys the power of the disease within twenty-four hours. There appears to be no limit to the amount which may be given, for a gentleman between seventy and eighty years of age took twenty-one powders in sixty-eight hours without any depressing effect if accompanied with stimulant. The temperature then being normal, no more were given for some hours, when, the temperature rising to 102°, the treatment was recommenced, with the result that in about twelve hours the body heat was 99°. This plan of treatment saves much writing, dispensing, and sending out medicines on one's return home, for one simply takes a packet of powders. A powder can be divided for a child and made into four for a baby. In all cases I order a milk (perhaps with soda water) diet only, and insist on champagne or whisky every three hours. Many have said to me that they feel, in about ten minutes after taking a powder, the feverishness much lessened, remaining so for an hour or more. I see that salicylate of antipyrin and benzole are highly recommended. I trust, if we are to have any more of this wretched epidemic, an acute fever of the nervous system, a more perfect plan of treatment than there seems to exist will be found. For the cough, headache, backache, and other aches accompanying influenza and its convalescence I find a pill of a quarter of a grain of cannabis indica very useful with adults, given every hour, if necessary, for a consecutive six hours or more.

I am, Sirs, yours faithfully,

Canterbury, Jan. 25th, 1892. PUGIN THORNTON.

P.S.—Has anyone not using drugs trusted to body-sponging for reduction of temperature?

To the Editors of THE LANCET.

SIRS,—Though unwilling to add to the long list of reputed remedies for influenza, after seeing Dr. Althaus' letter in THE LANCET of last week advocating the use of the salicylate of antipyrin, I would like to call your attention to salicylate of bismuth, which I have used extensively during the last and also the present epidemic, with marked benefit. It is especially valuable in two classes of cases—namely, in young children, and also in those cases where gastro-intestinal symptoms are troublesome, one dose usually being sufficient to allay the vomiting. Though I have carefully examined for toxic symptoms, and inquired after them, I have found none, which is by no means a small advantage. It is administered in a mixture suspended in mucilage and flavoured with orange, lemon, or ginger, &c.

I am, Sirs, yours truly,

HERBERT H. HORDEN, M.D., L.R.C.P.

Water-lane, Jan. 27th, 1892.

THE MEDICAL DEFENCE UNION.

To the Editors of THE LANCET.

SIRS,—I have already told Dr. Phillips that I do not quite recognise my speech in his report, and I certainly did not mean to accuse Dr. Woods of imputing *mala fides* to anyone. If you will allow me, I should like to state my argument thus. The Medical Defence Union is admittedly very useful, but it can only be managed successfully by a strong and permanent council. This council must have the confidence of the members, and those who cannot trust it had better secede. There is plenty of room for a second organisation working on similar lines, and the difficulties of management are diminished where the organisation is confined to one locality and the office-bearers have personal knowledge of the men with whom they have to deal. I believe a thousand members is quite large enough for stability and efficient working.

I am, Sirs, yours faithfully,

Birmingham, Jan. 23rd, 1892. ROBERT SAUNDBY.

PATHOLOGICAL CONDITIONS IN THE MAMMA ASSOCIATED WITH CANCER.

To the Editors of THE LANCET.

SIRS,—Mr. Roger Williams remarks that the changes described in the breast tissue, apart from the carcinomatous tumour, by Mr. Johnson and myself at the Pathological Society on Jan. 5th, were known to Sir Astley Cooper; but the passages which he quotes from that surgeon's works do

Digitized by Google

not prove this. They alone show that he was aware of the well-known invading character of scirrhus, and was familiar with the lengthened prolongations spreading outwards from the more localised mass, a condition so frequently found, but one entirely aside from the subject of the papers. Also, the primary origin of scirrhus in outlying parts of the breast was not under discussion. Shortly before reading my paper I heard of Heidenhain's work, but had not had an opportunity of referring to it. His observations and the conclusions which he arrived at are apparently much the same as those to which I was led. My friend Mr. Johnson did refer to Heidenhain's observations on the pectoral fascia. I take this opportunity to correct an obvious printer's error in your report in THE LANCET on page 90—viz., œdema for adenoma.

I am, Sirs, yours truly,

CECIL F. BEADLES.

London County Lunatic Asylum, Colney Hatch, N., Jan. 24th, 1892.

SANITATION AT CALAIS.

(FROM OUR SPECIAL CORRESPONDENT.)

ABOUT three hundred thousand travellers cross the Channel and pass through the town of Calais during the course of the year. In the year 1889, in consequence of the Paris Universal Exhibition, the actual number of passengers who availed themselves of the Calais route amounted to 332,230 during the first eleven months of that year. This enormous figure suggested the advisability of some inquiry as to the sanitary condition of Calais. In THE LANCET of Dec. 21st, 1889, the result of the investigations made at that time were published. Two years have now elapsed, and on again going over the same ground I am pleased to be able to report progress. The articles published by THE LANCET were carefully translated into French by an official of the Calais municipality, and read and studied by the local authorities, with the result that the work of sanitary improvement has been pressed forward with considerable energy. It may be remembered that, writing from Calais at the end of the year 1889, I described how the old historic town of Calais had been united to the new industrial suburb of St. Pierre, where are situated the celebrated tulle manufactories. The total population was 58,000, of whom 44,000 belonged to St. Pierre. Of these, 5000 were foreigners, comprising some 1500 British subjects, who are residents permanently established in Calais. The town is provided with pure though somewhat calcareous water from Guines, but a certain number of private wells still exist; and I must repeat to-day what I said two years ago—namely, that the authorities should be armed with power to close all such private wells. Fortunately, however, Calais is so low—some portions of the town being below the level of the sea—that the water in these private wells is often brackish; it can, therefore, only be used for cleaning purposes.

The general aspect of Calais and St. Pierre has greatly improved. Formerly there were hardly any sewers. The slop water from the houses flowed into the streets; if there was a sufficient fall, and the gutter was not blocked, it gradually found its way into the port, but very often the slop water stagnated in the streets, formed pools of fermenting matter, and gave off objectionable odours. Some sewers had, however, been constructed of late years, amounting in 1889 in total length to 6320 metres. Since then—that is to say, in the brief space of two years—sewers to the extent of 4540 metres have been added. This is a notable improvement, and brings the total length of the Calais sewers up to the respectable figure of 10,860 metres. Most of these sewers are eighty centimetres in width, and made of compressed concrete. At distances not greater than fifty metres one from the other, and on both sides of the streets, are openings from the gutters to the sewers. The slop water from the houses still runs into the gutters, but it soon finds its way to the sewer, and no longer stagnates in the street. This is in one sense preferable to draining into the sewer, for there is no direct communication from the houses to the sewers, and no danger of the sewer air travelling up the drain pipes into the houses. The sewers ventilate into the open streets. The new sewers are also very useful in preventing the floods that frequently occurred in some parts of the town. The greater portion of the sewers built since 1889 have their outfall in the tidal basin of the port; but some of the sewage falls into the canal near the citadel. There it is locked in until such time as the condition of the tide admits of the canal water being run out into the harbour. To drain into a harbour is bad enough, but to drain into a canal is infinitely worse. Monsieur A. Dagniault, the town engineer, explained that it was impossible to manage otherwise. A great portion of Calais being below the level of the sea, it was not possible to obtain a fall in other directions. Of course what is needed is a pumping station to raise the sewage, and thus to artificially create the necessary fall. The new Calais, which includes St. Pierre, is surrounded by fortifications and a moat. The old Calais is surrounded by huge docks and by canals, and to construct a main sewer through this double series of obstacles is no easy matter. When the new fortifications and the new docks were built, no one seems to have thought of making any sort of provision for the drainage of Calais; yet it might have been foreseen that as the population increased, as the knowledge of sanitation spread, objections to draining into the port would become more and more emphatic.

For the moment, however, the population of Calais is not increasing; on the contrary, there has been a notable decrease in the number of inhabitants. This is due to the termination of the greater part of the works for the building of the fortifications, new harbour, and docks. Also, the tulle manufactories not having prospered of late, a great many of the hands have had to seek work elsewhere. A large proportion of these artisans have obtained employment in Poland, principally in the neighbourhood of Warsaw, where certainly they will not find better sanitation than at Calais. According to the census taken on May 31st, 1886, there were 58,969 inhabitants at Calais and St. Pierre. The census taken on April 1st, 1891, showed that the population then amounted to only 56,867. This is a falling off of 2102 persons; but, as during the last two years there have been 1206 more births than deaths, we may conclude that at least 3300 persons have left Calais in that lapse of time. Many of them were Italian navvies whose labour at the new port was no longer required. For a town so sparsely populated—all the new streets are broad, the houses low, and many of the streets mapped out are not yet built upon—the death-rate is high. It amounted to about 22·2 per 1000 in 1889 and 22·9 per 1000 in 1890. Calais is healthily situated, constantly exposed to the fresh sea breeze, swept and purified by the four winds of the heavens; still Calais has a death-rate much higher than London, notwithstanding the overcrowding, the vice, the misery, and the fearful fogs of our great metropolis.

Calais, moreover, retains cesspools. These are emptied with some care by pneumatic suction. This is not produced by a portable steam engine, as in Paris, but by a hand-pump. In Paris the air escaping from the cesspool is passed through the fire of the engine and thus rendered innocuous. At Calais a special fire is lit in the street in a very simple contrivance the shape of a handbell or of an inverted wine-glass. The bell part is put on a smooth piece of ground or pavement. An aperture in the centre enables a pipe to be screwed on which joins the pipe that is laid from the portable tank to the cesspool. The upper part of the apparatus, which I might call the handle of the bell, is a circular metallic tube about four inches in diameter and a foot long, perforated on all sides with small holes. At the bottom there is a little grate. This pipe is filled with charcoal, and when the charcoal burns it consumes the air escaping from the cesspool by the pipe which brings it to the bell portion of the apparatus beneath the fire. In this way a cesspool can be emptied in the daytime without causing a nuisance. The contents of the cesspool are then conveyed to tank barges, which, by canal, travel to Belgium, where there are large works for the manufacture of human guano. Needless to observe, the emptying of the cesspools costs each householder a certain sum, which sum, paid as a tax for sewers, would probably suffice to cover the interest on a loan levied to carry out a proper and complete scheme of drainage. There must be some low-lying district where a sewage farm could be established or a point on the coast where the sewage outfall could be

Digitized by Google

brought without injury to bathing. Of course it will be difficult to urge the abolition of cesspools and to propose direct drainage into the sewers while these latter have their outfalls either among the shipping in the port or in the stagnant water of the canals.

In the old inner port, known as the Basin du Paradis, close to the ancient but now abandoned town railway station, there is a sewer outfall. When the tide runs out a filthy, greasy, black mud is exposed, which gives off foul odours. Here are a great number of fishing smacks. The owners of these vessels still continue to look with favour on the filth by which they are surrounded; it makes a soft bed for their boats to rest upon when there is no water in the port. The town authorities more than two years ago had offered to send in a deredger to remove these sewer deposits; the fishermen refused the offer, so that the dirt remains, much to the annoyance of all visitors to Calais.

The fishermen's quarter near the lighthouse, called the Courgain, remains in the same picturesque and insanitary condition as when I described it last. The houses are still devoid of any sort of sanitary convenience, and utensils containing night soil are brought out every morning into the streets and emptied into a large drain in the middle of a somewhat elegant kiosk. A scavenger flushes this place once a day, and all that has been emptied into it flows into the port among the shipping. On the other hand, this, the slum of Calais, is a marvellous picture of cleanliness. The fishwives, with their neat hand-knitted woollen stockings, thick, short, clean skirts, their wooden clogs, and caps of spotless white, are ever engaged scrubbing the floors of their little houses, washing down the walls, and sweeping the narrow street. On the whole, the quarter is healthy in spite of the total absence of drainage. The wonderful neatness, order, and cleanliness of the inhabitants compensate in a great measure for the smallness of the houses, the narrowness of the streets, and absence of closets or drains.

Now that the fortifications are finished, that the heaviest work and expenditure for the new port and docks are also completed, perhaps more thought will be devoted to sanitary improvements. The fact that in two years the sewers have been augmented in length from 6320 metres to 10,860 metres is evidence of good intentions. There is, I have shown, still much to be done, but what has been achieved during the last two years gives good promise for the future.

BIRMINGHAM.

(FROM OUR OWN CORRESPONDENT.)

Health of the City.

UNDOUBTEDLY the late severe weather is responsible for a large increase in the number of pulmonary affections, so much so that the death-rate rose last week from 19·4 to 26·6. Only six deaths were certified as due to influenza, as compared with seven in the preceding week, facts which show that this dire disease is not as yet present in an epidemic form among us. At the same time there is a large amount of sickness generally, many practitioners being sorely overworked by the exceptional strain. For instance, the parish authorities report that the out-door medical relief has gone up 35 per cent. above the average. The Health Committee have printed and circulated a hand-bill among householders, detailing the symptoms, treatment, and means of prevention of influenza. The most important part of the advice given is, "Send for the doctor without delay," a common-sense view which commends itself to most intelligent minds.

Hospital Saturday Fund.

The first meeting of the Board of Delegates for the administration of the Birmingham Hospital Saturday Fund was held at the Council-house on the 25th inst. under the presidency of the Mayor (Councillor Lawley Parker). A sketch of the history of this movement for the past nineteen years was given, and it was pointed out that in 1891 a legal constitution became necessary for the purpose of carrying out the new plans, and that the association was registered on Dec. 29th as a company. The purchase of a property at Tyn-y-coed, near Llandudno, was effected for the sum of £7500, this amount being generously given by Miss Stokes, the object being to establish a convalescent home in connexion with the fund. It is intended that the sum of £10,000 per annum shall be given to the hospitals for the gratuitous work they do, and that the remainder of the money shall be devoted to the maintenance of the home. Some interesting figures were given by Mr. Smedley, the secretary, with whom the idea originated of making this departure, of such vast importance to the working classes of the city. He showed that the sum contributed by the working classes to the hospitals in 1867 was £500, in 1890 it was £19,000, and he believed that it would be still greater as years went on. Some very significant figures were also given with regard to the sources of the subscriptions. Thus between £19,000 to £20,000 came from working men, £12,000 from private subscriptions, £4000 from country subscriptions, and about £4000 from Hospital Saturday. The total income of the hospitals in 1890 was £55,373, of which £5667 came from legacies, donations, and investments. The incidence of this new departure will bear strongly on the provident principle, and will have an important effect on the present working of the hospital system.

Changes in Appointments.

Dr. Suckling has resigned the post of physician to the Workhouse Infirmary. The salary is £200 a year. Dr. G. F. Crooke, pathologist to the Queen's Hospital, is a candidate for the appointment. Mr. Augustus Clay has resigned the post of casualty surgeon to the Queen's Hospital. The promotion of Mr. Haslam to the honorary staff of the General Hospital has left a vacancy for an assistant surgeon. Among the candidates are the present house surgeon, Mr. Albert Lucas, Dr. Felix Vinrace, and Dr. B. F. Jordan. The appointment will be made on Feb. 5th.

The Children's Hospital.

The annual meeting of this charity was held at the Medical Institute on the 25th inst. Mr. H. Wiggin, M.P., presided. The thirty-first annual report was presented, and showed that the number of in-patients for the year was 841, out-patients 11,999, casualties 832, and home patients 22. The detention rate was 21·3 days, the death-rate 10·4 per cent., the cost of maintenance of patients 2*s.* 9*d.* per week, and of officers 8*s.* 3*d.* per week. The accounts showed that the income was £80 less than the expenditure. The magnificent gift of a convalescent home at Moseley by Mr. Cadbury will allow of twenty beds being always at the disposal of the hospital. The usual votes of thanks were passed.

Birmingham, Jan. 29th.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

Influenza.

THERE have been many cases of influenza in and around the city, and when it has been followed by pneumonia or other chest complications it has been very frequently fatal. In the majority of cases recovery follows, but the inconvenience arising from its prevalence is very great, especially among large bodies of men like the police and postal officials. The weather has been somewhat milder during the past week, which will probably have some effect in diminishing the more serious complications.

One Year's Result of the Infectious Diseases Notification Act.

At the last ordinary meeting of the Medical Institution Dr. E. W. Hope, the assistant medical officer of health, recounted the results of the working of the Notification of Infectious Diseases Act in Liverpool from its first adoption on Sept. 1st, 1890, to Sept. 1st, 1891. Liverpool was slow to adopt the Act, and local practitioners had grave misgivings as to its working, which, however, have been dispelled. Simultaneously with the adoption of the Act a small sub-committee of the Medical Institution was appointed to confer with the medical officer of health as to the most suitable form of certificate by which the notification could be made. This form was usefully designed to enable the certifying practitioner to supplement the notification with additional information, which supplemented form, when filled up, obviated much inconvenience and irritation. Arrangements have been made between the medical depart-

Digitized by Google

ment and the School Board by which every absence from school of a scholar alleged to be suffering from infectious disease is reported by the master or mistress to the medical department; while, in return, the latter sends information daily to the head master or mistress of any school attended by scholars coming from houses in which infectious disease is ascertained to exist, this being a double check against the spread of infection. This interchange of information has enabled measures to be taken with regard to several localised outbreaks of a somewhat serious nature; and in one case what threatened to be a formidable outbreak of typhus fever was promptly and effectively dealt with. Dr. Hope's paper contained additional valuable details, and it is satisfactory to note that the notification of these diseases here has been successful.

Dangers from attending Funerals.

Liverpool has always been in advance in the matter of funeral reform, and particularly in that phase of it which is now attracting so much attention. At the funeral of a well-known local surgeon, in 1879, which was largely attended by his professional brethren, the service at the graveside was considerably shortened. It happened to be Christmas Eve; the weather was intensely cold, and, in addition to this, the rain fell in heavy showers. The same practice has been followed since in not a few instances, and at the funeral of the late much-respected chaplain of St. James's Cemetery, the Rector of Liverpool, who officiated, warned all present, before leaving the chapel, to keep their heads covered at the grave. No sight can be more distressing than to see aged and bald-headed men standing bareheaded round a grave in such weather as has recently prevailed, and there seem good grounds for hoping that the senseless practice may become obsolete. Another well-known clergyman recently contracted a very severe illness from attending a funeral.

Liverpool, Jan. 27th.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

The Proposed Albert University for London.

THE opposition to the proposed new university upon the lines laid down for its establishment is quite as strong here from the Victoria University authorities as in the metropolis from the London University, though it takes somewhat different lines in the two places. The Victoria University and its constituent colleges in Manchester, Liverpool, and Leeds in the memorial which they have issued base their objections chiefly on medical grounds. They endeavour to show "that the provisions of the Draft Charter of the Albert University will, if sanctioned by Parliament, seriously endanger the maintenance of the standard of medical degree examinations, which the Victoria University has sought to uphold, more especially with regard to preliminary general qualifications in arts and to preliminary special qualifications in science; and furthermore, that these provisions will seriously affect the prosperity of medical schools outside London, upon the establishment and development of which large sums liberally contributed by the public have been spent, by inducing students to betake themselves by preference to London, where a medical degree will be obtainable with less effort and on easier terms." In the matter of university extension lectures the Victoria University is doing a good work. This session there are nearly a hundred centres of instruction in this and the neighbouring county of Yorkshire, many of the courses being given by arrangement with the County Councils.

Owens College.

The College has got well into work again after the short Christmas vacation, the most important event having been the installation of the new Professor of Pathology, Dr. Delépine. As previously reported in these columns, the vacancy arose by the transfer of Dr. Dreschfeld to the chair of Medicine, rendered vacant by the resignation of Professor Morgan. The chair of Pathology in Owens College is now one of the best endowed in the kingdom, out of funds bequeathed by the late Daniel Proctor, after whom the professorship is named. Dr. Delépine comes to us from London, with a good record, and his inaugural address was listened to by a large audience. Very different now is the position of pathology in the curriculum of the student to that of a dozen years ago. When Dr. Dreschfeld first commenced work as lecturer on pathology the students attending his class could have been counted on the fingers; now it attracts all the best men, and the courses are as fully attended as those of any other subject.

The Disposal of Town Refuse.

A subject which has excited a considerable amount of interest in the city generally, and especially amongst those who take interest in municipal work, is the disposal of town refuse. The corporation proposed to erect "destructors" at various points to deal with this material, believing that the work can be accomplished without nuisance, but at each suggested site a great cry of opposition has arisen from the adjacent residents. Public meetings have been held, memorials largely signed by members of the medical profession and other methods of organised opposition have been put in operation, and at the last meeting of the City Council the subject was discussed at length without any conclusion being arrived at. There would appear to be some misapprehension abroad in the public mind, and it appears to be thought that the Corporation intend dealing with excrementitious matter at these destructors. If this be so, nuisance will inevitably arise; but if material other than this only is to be dealt with, then the operations can be conducted without danger of annoyance; at least, such is the report from other towns. A subject mixed up with this is the provision of water-closets in place of the system of pails which is so largely in use amongst cottage property here, and which is without doubt the source of much nuisance and insanitary conditions.

Pauper Dietaries.

It is notorious that the dietaries of the different workhouses of the country vary considerably both in quality and quantity. A conference of representatives of the chief Poor-law authorities of this district has just been held to consider the question, apparently at the instigation of the Local Government Board. Dr. Rhodes, of the Chorlton Board of Guardians, has taken considerable trouble in giving prominence to this subject, and he took a leading part in the proceedings of the meeting, which was presided over by another well-known medical man, Mr. Bowring. In the result it was recommended that the following should be a sort of standard dietary for the four Boards of Guardians represented:—Dinner: Sunday—Five ounces of meat (weighed uncooked), six ounces of suet pudding, eight ounces of potatoes. Tuesday and Thursday—Four ounces of cooked meat, twelve ounces of potatoes, four ounces of bread. Wednesday and Friday—Thirty ounces of pea-soup and six ounces of bread. Monday and Saturday—One pint of potato hash, three ounces of meat (weighed uncooked), twelve ounces of potatoes, half an ounce of onions, and four ounces of bread. Supper: Tuesday and Friday—One pint of gruel, five ounces of bread, two ounces of cheese. Other days—Six ounces of bread and a pint of cocoa. It was also suggested that a special low dietary might well be adopted for those able-bodied men who were nothing but a nuisance and would not try to work.

Juvenile Drunkenness.

A shocking case of drunkenness in a child was recently before the city magistrates. The mother of a little girl only three years old, together with another woman, were convicted of giving the child, in a public-house, whisky and port wine until it was helplessly intoxicated and had to be taken to the infirmary for medical treatment, so alarming was its condition. The mother was sent to prison for fourteen days and the other woman for a week; but what shall be said of those persons at the bar of the public-house who, it is stated, supplied the intoxicants?

The Royal Infirmary.

At the monthly meeting yesterday of the Infirmary Board a vote of condolence was passed, to be forwarded to Her Majesty the Queen and their Royal Highnesses the Prince and Princess of Wales, on the death of the Duke of Clarence and Avondale. Her Majesty is a patroness of the Infirmary, and it has special permission to use the prefix "Royal." It was stated that the Board now have various plans under consideration for the proposed extension; but it is not said when these plans will be open for inspection, or when the public meeting is to be summoned to give sanction to any such extension.

Digitized by Google

Influenza.

As stated in THE LANCET last week influenza, though present in the city and suburban districts, is of a comparatively mild character, is so far of no very widespread prevalence, and has shown a very different tendency to the outbreak of last year to rapid diffusion and spread. Although the evidence as to its infectious nature is apparently incontrovertible, there must be other factors at work, call them what we will, miasmatic, climatic, or meteorological, of which we are profoundly ignorant, else why this striking difference in its dissemination in different parts of the country and at different times?

Manchester, Jan. 26th.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

The Influenza Epidemic.

THERE is some abatement in the severity of the attacks of influenza reported in the northern counties, but the number attacked has decidedly increased. There has been a very high death-rate at Carlisle, 45 per 1000, as against 21 per 1000 in the corresponding fortnight last year. At Naworth Castle, near Carlisle, about thirty of the inmates have been attacked; of this number, fourteen were seized simultaneously. At Middlesbrough the disease is rife, and several prominent corporation officials have been laid up, and in the neighbouring district of Eston the medical officer reported the highest death-rate since the local board was formed, including in] the fortnight nineteen deaths from influenza and its complications; but the medical officer (Dr. Malcomson) said he had reason to believe that the fatalities from other diseases than those above-named were due to a previous attack of influenza. Before I leave the subject I may say that our local newspapers are now very much taken up with influenza "cures" and "curers." It is a general opinion, however, of the profession here that these ready writers contribute nothing of the least value as regards the cause or cure of the disease.

Newcastle Clinical Society.

This young and vigorous society gave its annual banquet, at the Crown Hotel in this city, on Thursday last, which was presided over by Mr. Walter Ridley, and well attended. The whole arrangements were complete, and creditable to the honorary secretary, Dr. George Murray. The guests represented all departments of the profession in the district. I was glad to see our venerable citizen, Dr. Embleton, present.

A Handsome Vaccination Grant.

Dr. Whamond, medical officer to the South Shields Union for the district of Jarrow and Hebburn, has received a grant of £100 from the Local Government Board; this is the ninth grant given by the Board to Dr. Whamond for successful vaccination.

The Royal Infirmary and Students' Fees.

A subscriber to the Newcastle Royal Infirmary points out that, while the Royal Infirmary is asking for funds to make up an apparent deficit of £2000, there are some 200 students paying the treasurer about £10 per annum each, which, if placed properly in the accounts, would make the present income sufficient to balance the outlay, and he asks why these fees are not included in the balance-sheet.

Curious Case of Aneurysmal Varix.

By the kindness of Mr. Frederick Page I saw an interesting case of varix now under his care at the Royal Infirmary. The patient, a miner aged about forty, a month ago received an injury to the neck requiring ligatures of the jugular to stop the hæmorrhage. A tumour consequently formed, and it is now as large as a duck's egg, and pulsating; the pulsating current apparently arises from the external carotid. I have not heard yet if any operative procedure is contemplated.

Bequests of the late Mr. John Coppin, J.P.

The late Mr. John Coppin, J.P., of Bingfield Hall, Northumberland, has, among other bequests, given the following:—To the Newcastle Convalescent Society, £500; the Natural History Society of Newcastle, for a curator, £2000; and to the National Hospital for Consumption, Ventnor, £500.

One of our Newcastle papers regrets to hear that Dr. Heath is lying seriously ill at his country residence, near Durham.

Newcastle-on-Tyne, Jan. 27th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Edinburgh Association for the Reform of Medical Education.

ONE of the points which this Association made in its statement to the Universities Commission bore upon the extraordinary prominence given to the subject of materia medica in the Draft Ordinance issued by the Commission. Other bodies, as well as this Association, have commented upon this. A counterblast to the Association's statement has now been prepared, insisting on the necessity of two examinations on this subject, one in pharmacy and pharmacognosy, the other in pharmacology and therapeutics.

Diseased Meat Case in Edinburgh.

At the end of last week, in the Edinburgh Police-court, an exceedingly bad case of selling diseased meat was before the sheriff. A butcher in town, the head of an old and prosperous business, is also a farmer, and it appears that towards the end of December last one of his bullocks died suddenly. The manager of the farm believed the animal died of splenic fever, and told his master so. The carcase was nevertheless ordered to be sent into town, and was disposed of in the owner's shop. The dead animal had been skinned by a shepherd who had a slight wound on his arm, through which he was inoculated, and as a result died. The examination of the viscera showed the case to be one of anthrax. The butcher pleaded guilty, and was fined £20. So far, no further harm has been found to be associated with this case; but the possibilities of danger seem almost infinite when the virulence of the poison is borne in mind and the numerous hands, baskets, and dishes which must have been in contact with the various cuts, and the numerous mouths and stomachs into which bits of that carcase must have been introduced, are calculated. The possibility of such meat getting into the market shows the utter inadequacy of present laws and arrangements.

The Health of Edinburgh and Leith.

The mortality last week was 102, making the death-rate 20 per 1000. Diseases of the chest accounted for 50 deaths, and zymotic diseases for 5. The intimations for the week were: typhus fever 1, typhoid fever 4, diphtheria 3, scarlatina 17, and measles 20. The deaths in Leith last week numbered 35, making the death-rate 26 per 1000.

The Edinburgh Medico-Chirurgical Society.

At the meeting of this Society last week two cases of empyema in adults cured by drainage were shown, and Professor Struthers showed an interesting example of "rider's bone," the condition being an ossification of the tendon of the adductor longus on both sides. Dr. J. W. Ballantyne made a careful communication on an investigation into the Spinal Column in the Infant, and Dr. Sloan recorded the features of an extreme case of Hystero-catalepsy followed by insanity and recovery. A number of members offered remarks on both papers.

Edinburgh, Jan. 26th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Typhoid Fever in Dublin.

A CONFERENCE was held in Dublin last week on the subject of the prevalence of typhoid fever, and after the matter had been fully discussed the following resolution was adopted: "That this meeting appoint a committee empowered to draft a memorandum dealing with any facts within the cognisance of such committee bearing on the prevalence of typhoid fever in Dublin, for the consideration

Digitized by Google

of the Public Health Committee, with a view to induce the Public Health Committee to make a special investigation into the causes of typhoid fever." The following were appointed to act on a subcommittee of the Dublin Sanitary Association in preparing the memorandum referred to, their draft to be submitted to a future meeting of the conference—viz., Drs. Emerson Reynolds, C. Nixon, and Messrs. Drew and Maunsell.

Trinity College Tercentenary.

Next year being the tercentenary of the University of Dublin, rumours were industriously circulated by interested parties that it was the intention of the board to relax the College rules respecting term and degree examinations on the occasion of the tercentenary celebration. The Provost and Senior Fellows, however, have intimated that they do not intend this year to allow terms or grant degrees without examination, being of opinion that such action on their part would tend to lower the estimation in which the education given in Trinity College is held by the public.

National Eye and Ear Infirmary, Dublin.

During the past year, except for a few weeks in spring, the hospital has been overcrowded, and there have frequently been more patients in the institution than beds. The committee have appealed for funds to increase the size of the hospital, but the response, so far, has fallen short of the amount (£7000) required. During the year the oft-debated question of the amalgamation of the hospital with St. Mark's has been again under the joint consideration of the committee and of the board of St. Mark's Hospital, but nothing definite has yet been decided.

Galway County Infirmary.

This institution is again closed owing to a want of agreement between the governors of the infirmary and the authorities of the Queen's College. In the meantime the matter is serious for the college students, who may lose an academical year if some arrangement is not at once carried out. A memorial has been sent on behalf of the medical students to the Council of the Queen's College, but the result has not yet been made known.

Death of a Dublin Centenarian.

Mrs. Mary McDonald died in Ormond Market last week aged 102 years. Deceased was born in the Market in 1790, and during her entire life never slept outside the precincts.

Cork Union.

Mr. Runciman has been appointed medical officer of one of the Cork dispensary districts, vacant by the death of Dr. Harvey. There were seven candidates. Mr. Runciman has resigned the appointment of house surgeon to the Cork South Infirmary, and has been succeeded by Mr. Jackson.

Hospital for Consumption and Diseases of the Chest, Belfast.

The annual meeting of this charity was held on Jan. 21st. From the medical report I learn that there were 1101 new extern and 53 intern patients during the past year. There is a balance in hand of £68 2*s.* 4*d.* for the current account. Under the head of building fund the committee have £4227 11*s.* 1*d.*, which includes the donation of £2700 given by Mr. Forster Green for the ground for the new hospital at Newtownbreda. Captain McCalmont, M.P., who presided, in acknowledging a vote of thanks, said it seemed to him a matter requiring explanation that a sum of about £16,000 was voted by Parliament for the support of hospitals in Dublin. He had no wish to deprive the Dublin hospitals of their grant, but he thought that a city like Belfast, which contributed so much larger an amount to the revenue, and which contained a larger working population, had a fair claim to a similar grant, and he would promise to do his best, when Parliament met, to obtain a satisfactory explanation of the present arrangement.

The Ulster Medical Society.

At the third meeting of this Society for the present session communications were brought before the members by Dr. Cecil Shaw on the Treatment of Phthisis by Intralaryngeal Injections, by Dr. J. A. Lindsay, who gave a summary of fifty cases of Chronic Valvular Disease of the Heart, with special reference to Prognosis and Treatment, and by Dr. W. M. Killen, who read short notes of the Treatment of Puerperal Septicæmia as practised by him in a recent case. Dr. Killen also described the Treatment of Ophthalmia Neonatorum as practised at the Ulster Eye, Ear, and Throat Hospital.

Outbreak of Typhus Fever in Armagh.

At a meeting of the board of guardians, held on Jan. 26th, it was reported that in the fever hospital of the workhouse there are two cases of typhus fever, and that three other cases would be admitted. In a letter to the board their medical officer, Mr. Robert T. Herron, pointed out the fact that the patients had come from most insanitary dwellings; indeed, he said the place from which a woman with the disease was removed would not make a respectable pig-sty. The disease has not visited Armagh since 1864, and by vigorously pointing out how it can be prevented, Mr. Herron is doing good service in the cause of preventive medicine.

Death of Dr. John King Maconchy.

I have heard of the death from influenza of Mr. Maconchy, M.B, F.R.C.S.I, which occurred at his residence, Downpatrick, on Jan. 25th. He was surgeon to the Down Infirmary, the County Down Lunatic Asylum, and the prison. Dr. Maconchy for many years was the leading medical practitioner in the southern part of the county Down. He was an able surgeon and a man of all-round ability, and had developed a large private and consulting practice.

Jan. 27th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Antipyrin in Erysipelas.

IN the course of an epidemic of idiopathic facial erysipelas which visited the barracks at Syra, Dr. Fonstanos, medical officer to the hospital, was led to employ antipyrin in the treatment of cases of this disease, some of which were complicated by pneumonia. The results obtained by the method were so satisfactory and marked that he goes the length of speaking of the drug as a specific in this affection. Its action in lowering temperature was in these cases of erysipelas well brought out, and through this and the abundant perspiration which accompanied it a notable staying of the inflammatory process was very evident, due perhaps to the vigorous elimination by the skin of the streptococcus in great quantity. In every case during the epidemic in which recourse was had to the drug it did well, while complications were frequent in those in which other methods were employed. The dose, varying according to age and gravity of symptoms, was from twenty to sixty grains a-day, divided in powders and taken at frequent intervals.

Hiccough and Compression of the Phrenic.

A novel method of combating persistent hiccough was recorded by M. Leloir at a recent meeting of the Academy of Sciences. Some years back he was consulted by the parents of a little patient who was the subject for over a year before of a persistent and distressing hiccough, which recurred every half minute or so, and which had resisted every plan of treatment. M. Leloir then conceived the notion of compressing the phrenic, which he did between the sterno-clavicular attachments of the sterno-mastoid muscle. The compression was digital, and continued for three minutes, causing, however, considerable pain. As a result, the hiccough disappeared entirely, and has not recurred. Since then he has adopted the plan in several other cases of the kind, and always with complete success. The method is simple enough, and can be put in practice by anyone, and is, besides its utility, interesting as an example of the successful application of the researches of Brown-Séquard on inhibition.

Tuberculosis and the Common Earthworm.

It will be recollected that in 1880 Pasteur showed that the common earthworm could become the receptacle or habitat of the bacterium of charbon which was traceable to the cadavera of animals dead of this disease and buried in soil in the neighbourhood of which the worm lived. The possible relations between micro-organisms and these lumbricoids being thus established, MM. Lortet and Despeignes undertook some experiments with a view of elucidating a very probable connexion between these same lumbricoids and the bacillus of tubercle

Digitized by Google

In the result these observers have satisfied themselves that these animals—so universal and active—can become the hosts for several months of the tubercle bacillus, which loses none of its virulent properties by its change of abode. It is obvious that under certain circumstances the earthworm might readily become a too efficient medium for the propagation of this scourge of mankind. The experiments of MM. Lortet and Despeignes have a further interest in being the first instance, I believe, on record in which the "tuberculisation" of an animal belonging to the wide class of invertebrates has been demonstrated.

Medical Reform.

It has long been felt that the vast clinical fields of the Paris hospitals were hardly being made the best use of, and that much good work might be done by organising a curriculum of instruction over and above that of the Faculty of Medicine, and which might be carried out by the numerous and capable hospital physicians and surgeons who have no direct connexion with the School of Medicine, but who receive their appointments from the Assistance Publique which administers the hospitals, and which is itself a part of the Municipal Government of Paris. With this object a proposition is now before the Municipal Council which, if adopted, will organise a new field of clinical instruction complete in itself and entirely independent of the Faculty—corresponding, in fact, somewhat to the extra-mural schools in Scotland.

Paris, Jan. 27th.

Obituary.

SIR OSCAR CLAYTON.

SIR OSCAR M. P. CLAYTON, C.B., C.M.G., died on the 27th inst., at his residence in Harley-street, from exhaustion following upon prolonged attacks of gout, in a system debilitated by the severe illness from which he suffered twelve months ago. He was the eldest son of Mr. James Clayton, of Percy-street, Bedford-square, and was born in 1816. Educated at Bruce Castle, Tottenham, he entered at University College, and afterwards at Middlesex Hospital. He became a Member of the Royal College of Surgeons in 1838, and was elected a Fellow in 1853. He was extra surgeon to the Prince of Wales and surgeon in ordinary to the Duke of Edinburgh. He was also a Knight of the Order of Leopold of Belgium, and occupied the post of deputy-lieutenant for Middlesex and the Tower Hamlets. Sir Oscar Clayton contributed very little to the literature of medicine or surgery, but his skill and success in the treatment of patients coming under his care were generally acknowledged.

JOHN McDONNELL, M.D., F.R.C.S.I.

DR. MCDONNELL died on the 20th inst. at his residence, Upper Fitzwilliam-street, Dublin, at the great age of ninety-six years. Deceased was born in Belfast, and entered Trinity College, where he graduated in arts in 1818. A few years previously he was apprenticed to Mr. Richard Carmichael, the eminent surgeon, and in 1821 obtained the licence in surgery of the Royal College of Surgeons in Ireland. He studied in Edinburgh, London, and Paris, and obtained his degree of Doctor of Medicine in the University of Edinburgh in 1825. He settled in practice in Dublin in 1826, or thirteen years after he had commenced his professional studies. He was a lecturer on anatomy and physiology in the Richmond School of Medicine and surgeon to the Richmond Hospital. These two appointments he obtained by the influence of Mr. Richard Carmichael, who left him a sum of £5000 in his will. In 1847 he was appointed Professor of Anatomy to the Royal College of Surgeons, which post he resigned four years afterwards on being appointed medical member of the Poor-law Commission and afterwards medical member of the Local Government Board for Ireland. Dr. McDonnell was the author of the article on fractures in the "Cyclopædia of Practical Surgery"; and it is believed that he was the first in Ireland to use ether as an anæsthetic. The late Dr. Robert McDonnell, F.R.S., an eminent Dublin surgeon, was a son of the subject of this notice. The funeral took place on Saturday last, the remains being interred in the family burying-ground, near Drogheda.

MEDICAL TRIALS.

STEELE AND OTHERS *v.* SAVORY AND OTHERS.

THIS case was heard by Mr. Justice Romer on Tuesday and Wednesday last, when Mr. Moulton, Q.C., Mr. Costelloe, and Mr. Barnard Lailey appeared for the plaintiffs; the Attorney-General, Q.C., M.P., Mr. Haldane, Q.C., M.P., and Mr. J. R. Paget for the defendants.

Mr. Moulton, Q.C., in opening the plaintiffs' case, explained the circumstances out of which the action had arisen, referring particularly to the controversy which has for so long a time been in progress concerning the rights of Members of the College to take part in the election of the Council and the general administration of the affairs of the College. He commenced his narrative by a reference to the general meeting which was convened on March 24th, 1884, for the purpose of considering the proposals then made for a Supplemental Charter, and the resolutions then passed to the effect that it was not desirable to change the constitution of the College without the consent of the majority of the Members, and that it was inexpedient to prosecute an application for a Charter upon the lines of the draft then submitted.

Having thus noticed the origin of the dispute, he passed to the By-law No. xvii., which was called in question in the action, and read it in the following terms: "No business whatever shall be transacted nor any matter be discussed or debated, at any meeting or assemblage convened by or under the authority of the President or Council, or before or after the business thereof shall have commenced, other than the particular business or matter in respect of which such meeting or assemblage shall have been convened; nor shall any debate or discussion whatsoever be had or allowed at any meeting convened by the President or Council for the delivery of lectures or orations, either before or after the same shall have commenced or terminated. And no meeting or assemblage of Fellows or Members of the College shall be held in the Hall or Council-house of the College, or in any of its appurtenances, unless convened by or under the authority of the President or Council; and no Fellow or Member of the College shall advertise or convene or attend, or combine with others to advertise or convene or attend, any meeting or assemblage in the Hall or Council-house of the College or in any of its appurtenances not authorised by the President or Council. And any Fellow or Member of the College who may in any manner offend herein shall be liable to be restrained and excluded by the Council from attending any orations and lectures at the theatre, and from any use of or admission to the library and museum, and to be suspended from any or all other privileges which he may have as a Fellow and Member or a Member of the College for any such period as the Council may adjudge, or to removal by resolution of the Council from being a Fellow and Member or a Member of the College; and every Fellow or Member of the College who shall be removed as aforesaid shall thereupon forfeit all his rights and privileges as a Fellow and Member or a Member thereof."

He then read extracts from the correspondence which had passed between the plaintiffs and the secretary of the College to show that the Council proposed to put the by-law in force against the plaintiffs, and submitted that it was bad in law, and that the Council should be restrained by injunction from putting it in execution. The objections which he alleged to the by-law were two—(*a*) that it denied to Members of the College their rights, and (*b*) that it inflicted the unwarranted and unreasonable penalty of expulsion by the Council as the consequence of disobedience to the by-law. Upon this footing he claimed a threefold relief—(1) a declaration that the by-law was bad; (2) a declaration as to the Members' rights of meeting; and (3) an injunction to restrain the Council from acting on the by-law or in any way putting it in force. Under the second head of relief he asked more particularly for a declaration that reasonable use of the Hall of the College for

Digitized by Google

proper corporate purposes could not be taken away from the Members by a by-law, and in support of his case he submitted as principles of corporation law that the jurisdiction of the Council extended only to regulating the affairs of the corporation so as to produce the maximum advantage, and that the power of disfranchisement was inherent in the corporation as a whole, and could not be exercised by any select body unless committed thereto by the instrument which created the corporation and determined its constitution. He then glanced at what he suggested would probably be the ground upon which the defence would be rested—namely, a clause in a Charter granted to the College in 1843, which conferred upon the Council the power of making by-laws, and of enforcing them by expulsion, in the following terms: "That if it shall at any time hereinafter appear that any present or future Member, or any Fellow of the said College, to be appointed or admitted at any time after the expiration of the said first three calendar months from the date hereof, shall have obtained his letters testimonial or his diploma respectively by any fraud, false statement, or imposition, or that either before or after obtaining such his letters testimonial or diploma he shall have violated any by-law, rule, or regulation of the said College, then and in every such case, and after such previous notice to and such hearing of such Member or Fellow as under the circumstances the Council of the said College shall think proper, it shall be lawful for such Council to recall and to declare the letters testimonial or diploma respectively of such Member or Fellow to be void, and thereupon every such Member or Fellow shall cease to be a Member or a Member and Fellow of the said College, as the case may be, accordingly."

Commenting upon this clause, he suggested that the true construction would be not that the Council should have an unrestricted power to make by-laws and to enforce their observance upon members by the penalty of expulsion, but only such a power as would be consistent with the enjoyment by the members of all the rights which appertained to members of the old Company of Surgeons' rights, which, having been conferred by Act of Parliament, could not be taken away by Charter. Thereupon the Attorney-General objected that Members of the College of Surgeons could not claim the rights possessed by members of the old companies and guilds of surgeons which existed before 1800, because the old Company of Surgeons ceased to exist then. Upon this Mr. Moulton argued that the old Company had not in law been dissolved at that time, and that by the Charter of 1800 members of the present College of Surgeons were one body continuously with the members of the old companies. He further pointed out that under the Charter of 1800 there was no power of expulsion given to the Council.

Without calling on counsel for the defendants, Mr. Justice Romer gave judgment, dismissing the action with costs against the plaintiffs. He held that the corporation established by the Charter of 1800 was a new corporation, and that the only rights which the plaintiffs could claim were under that Charter; that the By-law xvii. was not *ultra vires;* and that power to make it was expressly given to the Council by the Charter of 1843.

ROYAL COLLEGE OF PHYSICIANS.

THE ordinary quarterly comitia of the College was held on the 28th inst., Sir Andrew Clark, Bart., President, in the chair.

Drs. Barratt, Bird, Fenn, and Kanthack were admitted to the Membership.

The College seal was affixed to the lists of those gentlemen who had recently passed the examinations for the Licence of the College and the examination in Public Health (conjointly with the Royal College of Surgeons).

A communication was read from the Secretary of State for War respecting the method now in vogue of conducting examinations for admission to the Army Medical Staff; and a committee was nominated to confer with a similar committee already appointed by the Council of the College of Surgeons upon the question. The committee consisted of Sir Joseph Fayrer, Dr. Cheadle, Sir Dyce Duckworth, Dr. Green, Dr. Farquharson, M.P., and Dr. N. Moore.

A letter was read from the Metropolitan Asylums Board asking for an authoritative opinion respecting the infectiousness of influenza, and the possible risks entailed by the conveyance of influenza patients in public vehicles. The President explained that he had counselled the chairman of the Board to sanction the use of the ambulances belonging to the Board.

At the request of the Executive Committee of the National Leprosy Fund, Sir Dyce Duckworth and Dr. Heron were reappointed to serve on the Special Committee to draw up a memorandum on the work of the Indian Commission and organise further inquiries upon the subject.

The vacancies on the Council caused by the death of Sir R. Bennett, and the retirement by rotation of Drs. J. Harley, Morgan, and Cheadle, were filled by the election of Drs. Maudsley, Bastian, Cayley, and Douglas Powell.

In compliance with a proposal from the Society of Arts, the Treasurer, Registrar, and Senior Censor were nominated a committee (with power to add to their number) to confer with that Society on the subject of obtaining a new scheme for awarding the Swiney prize. At present this prize is awarded quinquennially by the Society of Arts and the College of Physicians alternately to the author of the best work on jurisprudence.

The alterations in the by-laws proposed at the last meeting were enacted for the second time.

The President nominated a large and influential Committee for the Revision of the Nomenclature of Diseases.

The Annual Report of the Examiners for the Licence and a Report from the Laboratories Committee were received.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—The following candidates have passed in the respective subjects:—

Surgery.—W. H. Andrews, King's College; W. H. Cooke, St. George's Hospital; S. D. Gill, Queen's College, Birmingham; A. A. Macfarlane, J. N. Martin, and C. S. Palmer, St. Bartholomew's Hospital; W. Robinson, Middlesex Hospital; J. H. F. Way, St. Thomas's Hospital.

Medicine, Forensic Medicine, and Midwifery.—J. D. Hessay, Middlesex Hospital; R. L. Romer and H. G. White, St. George's Hospital.

Medicine and Forensic Medicine.—S. A. E. Griffiths, Middlesex Hospital.

Medicine and Midwifery.—B. S. Foulds, Charing-cross Hospital; J. P. Jones and H. W. West, London Hospital; C. Webb, St. George's Hospital.

Medicine.—C. R. Harper, Middlesex Hospital; A. G. Haydon, St. Bartholomew's Hospital; W. H. Waddington, Owens College, Manchester.

Forensic Medicine.—E. H. Bingley, St. Mary's Hospital; F. B. Lewis, London Hospital.

Midwifery.—W. C. Howle, Queen's College, Birmingham.

To Messrs. Bingley, Cooke, Griffiths, Harper, Haydon, Howle, Robinson, and White was granted the diploma of the Society, entitling them to practise Medicine, Surgery, and Midwifery, and enabling the holder to compete for medical appointments in the Army, Navy, and India Services, and for Poor-law appointments.

LAHORE MEDICAL COLLEGE.—PRINCE ALBERT VICTOR MEMORIAL HOSPITAL.—The formal opening of this wing of the Mayo Hospital was performed by his honour the Lieutenant Governor on the 1st inst. in the presence of a distinguished company. This memorial hospital is erected to commemorate the visit which his Royal Highness paid to Lahore in January, 1890. Such an addition to the Mayo Hospital was urgently required. The total outlay, including the furniture and general equipment of the buildings, is estimated to amount to 108,580 rupees. The accommodation provided consists of three separate buildings—a main block, a second block, and a third block.

LIVERPOOL INFIRMARY FOR CHILDREN.—The work of this institution has been satisfactorily carried on during the past year. There has been a decrease in the number of in-patients, but the beds have been as fully occupied as in the previous year. The falling off in the number of out-patients is rather a matter of satisfaction to the committee. They feel the resources of the infirmary have been, in this department, overtaxed. The balance-sheet shows a deficiency, including the deficit brought forward from last year, of £351 9*s.* 2*d.* The Convalescent Fund has been again of great advantage in supplementing the work of the infirmary. During the year sixty-seven patients were sent to West Derby.

Digitized by Google

THE ALVARENGA PRIZE.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about 180 dollars, will be made on July 14th, 1892. Essays intended for competition may be upon any subject in medicine, and must be received by the Secretary of the College on or before May 1st, 1892. It is a condition of competition that the successful essay, or a copy of it, shall remain in possession of the College.

AN AMERICAN HOSPITAL DESTROYED BY FIRE.—On the 21st inst., an appalling and destructive fire broke out soon after midnight at the National Surgical Institute, Indianapolis, a well and widely known establishment in America. The conflagration broke out in the offices, immediately over which were the wards for infants and mothers. The wildest confusion ensued. When the police and firemen arrived the buildings were burning fiercely. No attempt was made to save anything but the lives of the inmates. Accommodation was quickly found for the rescued patients in a neighbouring building, where cots were put up for them. Nineteen bodies had been recovered from the ruins.

ROYAL METEOROLOGICAL SOCIETY.—The annual general meeting of this society was held on Wednesday evening, the 27th inst., at the Institution of Civil Engineers, Great George-street, S.W., Dr. W. Marcet, F.R.S., vice-president, in the chair. The report of the council for the past year showed the society to be in a very satisfactory position. In May the library and offices were removed to more commodious premises at 22, Great George-street. Thirty-four new fellows were elected during the year, the total number on the roll of the Society now being 552. Owing to the absence of the president, Mr. Baldwin Latham, M. Inst. C.E., through an attack of influenza, his address on "Evaporation and Condensation" was read by the secretary.

BEQUESTS AND DONATIONS.—Mr. Denis Daly has left £100 to St. Joseph's Hospital for Children, and £300 each to Jervis-street, Mater Misericordiæ, and St. Vincent's Hospitals, Dublin.—Lord Ardilaun has given £100 to the Meath Hospital, Dublin.—The late Mr. John Hampson Jones of Lowndes-square bequeathed £1000 to the Manchester Royal Infirmary, and £500 each to the St. Mary's Hospital, Manchester, Salford and Pendleton Hospital, Brompton Hospital for Diseases of the Chest, Fulham Hospital for Cancer, Great Ormond-street Hospital for Sick Children, Convalescent Home, Orme-square, Fairford Cottage Hospital, and St. George's Hospital.—The workmen of Sir W. G. Armstrong, Mitchell, and Co., at Elswick, have contributed, *inter alia*, for the quarter ending Dec. 31st last, £269 8*s.* 11*d.* to the Royal Infirmary.—The workpeople of Messrs. J. S. Fry and Sons, Bristol, have contributed, during the past year, £456 19*s.* 6*d.* to the local medical charities, of which was apportioned £105 to the Royal Infirmary, and a like sum to the General Hospital, Bristol.

THE ADULTERATION OF MILK.—The appeal case of Brown v. Foot was heard before Mr. Justice Hawkins and Mr. Justice Wills on Tuesday last in the Queen's Bench Division. The appellant had been summoned under the Sale of Food and Drugs Act for selling milk adulterated with 15 per cent. of added water, and the question raised was whether the actual seller of the milk was the person amenable to the penalties imposed by the Act, or the master, who was said to be unaware of the adulteration by the servant. Reference was made to this curious point in a leading article in THE LANCET of Nov. 28th, 1891, p. 1230. Mr. Justice Hawkins said the question was whether or not a principal in a milk business was liable for adulterated milk sold by a man in his employ. The magistrate had held that the master was responsible and had convicted him, and he was of opinion that the conviction was right. He thought that a master, for all purposes, must be deemed "a seller" of the milk, as well as the man who was in charge of the cans, and it was not at all necessary to prove that he was cognisant of the adulteration to make him guilty of the offence of selling adulterated milk. The absence of cognisance might be a fact to take into consideration in imposing the penalty, and the case would go back to Mr. Bushby, so that he might reduce the fine if he thought fit; but it must be clearly understood that the Court, in sending the case back, did not in any way direct the magistrate to do anything. They simply affirmed the conviction and dismissed the appeal with costs.

THE guardians of the Salford Union Infirmary, Hope, near Eccles, have appointed a night superintendent.

APOTHECARIES' HALL OF IRELAND.—Mr. A. Jackson of Bandon has been admitted a licentiate of the Apothecaries' Hall.

SOCIETY OF ANTIQUARIES.—Surgeon-Captain G. Harley Thomas, F.R.C.S.E., has been elected a Fellow of the Society.

THE GRESHAM LECTURES.—The lectures on Physic will be delivered at Basinghall-street on Feb. 2nd, 3rd, 4th, and 5th, 1892, by E. Symes Thompson, M.D., F.R.C.P. The subject will be "The Nerves."

ST. BARTHOLOMEW'S HOSPITAL.—The re-drainage of this hospital is, we understand, being rapidly proceeded with, special care being taken to ensure the best results. Hassall's patent safety jointed pipes are being used throughout the entire work.

ACCOMMODATION FOR LEPERS AT POONA.—Mr. Keyser, C.S., Collector, of Poona, on Dec. 30th, 1891, laid the foundation stones of two new leper wards in connexion with the David Sassoon Infirm Asylum, towards the cost of the erection of which the widow of the late Mr. Nusserwanjee Maneckjee Petit has given Rs. 8000.

FRENCH MEDICAL CHARITIES.—A commission appointed by the French Minister of Agriculture has arranged to devote the following sums to the objects named:—100,000 francs to the French Hospital, Constantinople, 75,000 francs for the establishment of a hospital in Savoy, and subventions for a second urban ambulance station in Paris, and for a hospital for scrofulous children at Raphaël, similar to the one at Berck-sur-Mer.

BOMBAY MEDICAL UNION.—The eighth annual gathering of the Bombay Medical Union was celebrated at the Ripon Club on Tuesday, the 22nd ult. There were present about sixty members of the profession. Dr. Temuljee Bhikajee Nariman presided, and in the course of his speech, in proposing the toast of "The Medical Profession," gave a *résumé* of the work done in the year in connexion with the Union and in the medical world generally. Other speakers followed.

FOOTBALL CASUALTIES.—During a match last week between the Loughborough Wednesday and Willoughby Clubs a player fractured his clavicle.—In the same week, a similar accident occurred to a player at Pennygillaw, in a game between the Launceston Brigade second eleven and the Launceston Town second eleven. On Saturday, in a match at Totnes, between the home team and Torquay Athletics, the captain of the latter team fell; several other players fell upon him, and medical assistance being obtained, he was found to be suffering from concussion of the brain.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—A quarterly court of the directors of the Society was held on Wednesday, Jan. 13th. The chair was taken by Mr. Henry Lee, vice-president, in the unavoidable absence of the president, Sir James Paget. Two new members were elected, and the deaths of four reported. Grants to the amount of £1436 were made, to be distributed among the sixty-four widows and eighteen orphans receiving assistance from the Society. A fresh application for a grant was read from a widow, and assistance was given. The death of a widow in receipt of grants since 1879 was reported. The expenses of the quarter were £78.

THE CITY DISPENSARY.—The 103rd annual general meeting of the subscribers to this charity was held on Monday, at the dispensary, Watling-street, Mr. F. P. Alliston, C.C., Chairman of the Committee, presiding. The efficiency of the institution, the report stated, had been fully maintained. Consequent on the confiscation of the funds belonging to the parishes of the City, the dispensary had lost during the year a sum of about £150. In the course of the twelvemonth 12,606 patients had been treated, being, in comparison with the record of the previous year, an advance of 741. The accounts showed that, inclusive of a balance of £221 in the hands of the treasurer at the commencement of the year, the total receipts for the year were £1491, while the expenditure was £1308, a balance of £183 being thus left in the hands of the treasurer.

ROYAL DUBLIN SOCIETY.—The following have been elected members of this Society:—Daniel Corbett, jun., F.R.C.S., R. J. Montgomery, M.B., and Thomas J. Stafford, L.R.C.S.

NEWSVENDORS' BENEVOLENT AND PROVIDENT INSTITUTION.—The annual meeting will be held at the Memorial Hall, Farringdon-street, on Tuesday, Feb. 2nd, 1892, at 7.30 P.M., Alfred H. Hance, Esq, in the chair.

ROYAL UNITED HOSPITAL, BATH.—The annual meeting of the members of this institution was held on the 25th inst. The accounts in the report showed that the expenditure (including an adverse balance of £539 10*s.* 9*d.* from last year) amounted to £7307 10*s.* 6*d.*, the year closing with an increased deficit of £1179 11*s.* 10*d.* This state of things the committee accounted for by necessary wards at the hospital, extraordinary expenses on the building, &c., which will not recur for some years. There had also been a diminution in the receipts. The collections from places of worship have fallen off £155, donations are £328 less, while the amount of legacies available for current expenses has been £1099 14*s.*, as against £1631 18*s.*, a loss of £532 4*s.*

BIRKENHEAD BOROUGH HOSPITAL.—The annual meeting of the subscribers to this institution was held this week in the Town Hall, Hamilton square, Birkenhead, the Mayor (Alderman Willmer) in the chair. The report of the committee recorded that, while the year had been one of great expense, the income from ordinary sources had fallen short by £260, so that the balance due to the treasurer had been increased from £26 to £528. There was a gratifying increase in the workmen's subscriptions of £60. A donation of £1000 was made to the hospital by Mrs. Stevenson in memory of her husband, the late Dr. Stevenson, who had given his services to the hospital for the long period of forty-three years, and this sum, together with the balance received under the legacy of Mrs. Tait, amounting to £529, would be invested on behalf of the hospital.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—The following were elected office-bearers for 1892:—President: Dr. David Lloyd Roberts. Vice-Presidents: Drs. W. MacFie Campbell, James Armstrong, John B. Hellier, James H. Keeling, Stephen Nesfield, and John Scott; Messrs. Charles J. Wright and Arthur Jackson. Honorary Treasurer: Dr. William Walter. Council: Drs. James Braithwaite, William Alexander, J. Gordan Black, Samuel Buckley, Archibald Donald, John E. Garner, Thomas A. Helme, Thomas Johnstone, James Lambert, John M. H. Martin, John W. Martin, J. Frank Nicholson, George J. Robertson, T. Starkey Smith, and John Wallace; Messrs. John E Burton, J. Nelson Cregeen, Thomas Fawsitt, John F. Horne, Arthur H. Laver, W. Mitchell Roocroft, A. W. Mayo Robson, James Taylor, and Alfred T. Townley. Honorary Secretary: Mr. Henry Brigge.

MAYO HOSPITAL, LAHORE.—The Prince Albert Victor Wing of this hospital was opened on Friday, the 1st inst., by the Lieutenant-Governor. The building has been erected at a total cost of Rs. 108,805, and the accommodation which has been provided consists of three separate buildings. One, the main block, is a structure by itself with two general wards on the ground floor, each for ten patients, and on the upper floor private rooms adapted either for Europeans or native. The second block is intended solely for the treatment of cases of contagious and infectious disease, and will accommodate eight patients; and the third block is occupied as quarters for the nursing staff. His Honour, in opening the building, spoke in gratified terms of the high state of efficiency of the college, and made allusion to the appropriateness of the opening of the wing, which was designed to mark the loyalty of the province, taking place on Proclamation-day.

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN (40, Leicester-sq., W.C.).—8 P.M. Mr. C. S. Tomes: A Tooth attacked by a Fungoid Growth Post Mortem. The President will deliver his Introductory Address, which will be illustrated with Lantern-slides and Specimens
SOCIETY OF ARTS.—8 P.M. Professor George Forbes: Developments of Electrical Distribution. (Cantor Lecture.)
MEDICAL SOCIETY OF LONDON.—8.30 P.M. Professor W. Rose: The Surgical Treatment of Trigeminal Neuralgia. (Third Lettsomian Lecture.)

Tuesday, February 2.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.; Fridays and Saturdays at the same hour.
GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at same hour. Ophthalmic Operations on Monday at 1.30 and Thursday at 2 P.M.
ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.
ST. MARK'S HOSPITAL.—Operations, 2 P.M.
CANCER HOSPITAL, BROMPTON.—Operations, 2 P.M.; Saturday, 2 P.M.
WESTMINSTER HOSPITAL.—Operations, 2 P.M.
WEST LONDON HOSPITAL.—Operations, 2.30 P.M.
ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Consultations, Monday, 2.30 P.M. Skin Department, Monday and Thursday, 9.30 A.M. Throat Department, Tuesdays and Fridays, 1.30 P.M. Electro-therapeutics, same day, 2 P.M.
LONDON POST-GRADUATE COURSE.—Hospital for Skin Diseases, Blackfriars: 4 P.M., Mr. J. Hutchinson: Yaws and Allied Diseases.—Bethlem Hospital: 2 P.M., Dr. Percy Smith: Stupor.—Charing-cross Medical School: 8 P.M., Dr. Galabin: Cancer of the Uterus.
ROYAL INSTITUTION.—3 P.M. Professor V. Horsley: The Brain.
PATHOLOGICAL SOCIETY OF LONDON.—Dr. J. Griffiths: (1) Enchondroma following upon Hereditary Multiple Exostoses; (2) Dermoid Cyst attached to the Omentum.—Mr. S. G. Shattock: Inadequacy of the Current Terms applied to Suppuration, with a Proposal; and a Note on Peptone in Pus.—Mr. W. G. Spencer: Rupture of the Spermatic Vein in an Infant simulating Melanotic Sarcoma.—Dr. Norman Moore: Congenital Malformation of the Heart.—Dr. C. B. M. White: Mamma with Carcinomatous and Adenomatous Growths.—Dr. F. C. Turner: Fibrous Atrophy of one Adrenal.

Wednesday, February 3.

NATIONAL ORTHOPEDIC HOSPITAL.—Operations, 10 A.M.
MIDDLESEX HOSPITAL.—Operations, 1.30 P.M.; Saturdays, 2 P.M. Obstetrical Operations, Thursdays, 2 P.M.
CHARING-CROSS HOSTITAL.—Operations, 3 P.M., and on Thursday and Friday at the same hour.
ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M.; Saturday, same hour.
LONDON HOSPITAL.—Operations, 2 P.M.; Thursday & Saturday, same hour.
ST. PETER'S HOSPITAL, COVENT-GARDEN.—Operations, 2 P.M.
SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.
GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.
UNIVERSITY COLLEGE HOSPITAL.—Operations, 1.30 P.M.; Skin Department, 1.45 P.M.; Saturday, 9.15 A.M.
ROYAL FREE HOSPITAL.—Operations, 2 P.M., and on Saturday.
CHILDREN'S HOSPITAL, GREAT ORMOND-STREET.—Operations, 9.30 A.M. Surgical Visits on Wednesday and Saturday at 9.15 A.M.
LONDON POST-GRADUATE COURSE.—Hospital for Consumption, Brompton: 4 P.M., Dr. J. Kingston Fowler: Emphysema and Bronchitis.—Royal London Ophthalmic Hospital: 8 P.M., Mr. A. S. Morton: Retinal Affections.—Parkes Museum: 1 P.M., Dr. Louis C. Parkes: House Drainage.
OBSTETRICAL SOCIETY OF LONDON.—8 P.M. Specimens will be shown by Dr. George Beale and others. Annual Meeting. Election of four Honorary Fellows, and of Officers and Council. Dr. G. Paget Blake: Protracted Gestation. The President (Dr. J. Watt Black) will deliver the Annual Address.
SOCIETY OF ARTS.—8 P.M. Mr. T. Pridgin Teale: Dust, and How to Shut it Out.

Thursday, February 4.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M. Surgical Consultations Wednesday, 1.30 P.M. Ophthalmic Operations, Friday, 1.30 P.M.
UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Ear and Throat Department, 9 A.M.
ROYAL INSTITUTION.—3 P.M. Mr. A. S. Murray: Some Aspects of Greek Sculpture in Relief.
LONDON POST-GRADUATE COURSE.—Hospital for Sick Children, Great Ormond-st.: 4 P.M., Dr. O. Sturges: Illustrations of Heart Disease in Children.—National Hospital for the Paralysed and Epileptic: 2 P.M., Dr. Gowers: Bulbar Paralysis.—London Throat Hospital, Gt. Portland-st.: 8 P.M. Mr. G. Stoker: Chronic Glandular Diseases of the Nose and Naso-pharynx.
HARVEIAN SOCIETY OF LONDON.—Mr. Howard Marsh: Senile Tuberculosis.

Friday, February 5.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.
LONDON POST-GRADUATE COURSE.—Hospital for Consumption, Brompton: 4 P.M., Dr. J. Kingston Fowler: Cases of Valvular Disease.—Bacteriological Laboratory, King's College: 11 A.M. to 1 P.M., Prof. Crookshank: Anthrax (Gram's Method).—Charing-cross Medical School: 8 P.M., Dr. Galabin: The Modern Cæsarean Section.
ROYAL INSTITUTION.—9 P.M. Professor Roberts-Austen: Metals at High Temperatures.

Saturday, February 6.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; and Skin Department 9.15 A.M.
LONDON POST-GRADUATE COURSE.—Bethlem Hospital: 11 A.M., Dr. Percy Smith: Dementia.
ROYAL INSTITUTION.—3 P.M. Professor J. A. Fleming: The Induction Coil and Alternate-Current Transformer.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editors."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

We cannot undertake to return MSS. not used.

ENTERECTOMY.

WE have received from *Dr. H. W. Maunsell*, late lecturer on Surgery, Otago University, a long communication in reply to the statements put forth by Mr. Jessett in his letter to us published in our last issue. The consideration of Dr. Maunsell's communication must remain over till next week.

Mr. R. Robinson.—We are of opinion that such a broadcast distribution of post-cards is much to be reprehended.

Dr. A. B. Blacker.—Surgeon-Major Alcock's paper will be found in *Nature* of Aug. 21st, 1884.

Perplexed.—The climate of India would probably be suitable for such a case.

THE PREVAILING EPIDEMIC.

To the Editors of THE LANCET.

SIRS,—I enclose the latest feelings of an "influenza" patient. Kindly give insertion to the following if you can.—Yours faithfully,

Lower Seymour-st., W., Jan. 25th, 1892. HENRY APPLETON, M.D.

THE INFLUENZA FIEND.

Does he come from out the Orient,
Gathering poison by the way,
From the fever-swamps that fester
In the heat of far Cathay?

Do the powers of darkness aid him?
Does he fury gain and force
In expansive wind-swept deserts,
Or in camps of Tartar horse?

Does he draw the dread miasma
From the wide Mongolian plains?
Do the Steppes of Russia furnish
All his fierce, though shadowy, pains?

All I know, he left me prostrate,
Scarce with strength to lift a straw;
That he shook me in his talons,
And he struck me with his claw.

Windsor. A. COALE.

POLICE CAUTION.

WE are requested by Mr. Anderson of New Scotland-yard to publish the following:—

"Members of the clerical and medical professions are cautioned against a man who for some months past has been carrying on a system of fraud in various parts of London. His mode of proceeding is to call on clergyman and doctors, and introducing himself as being connected with a firm of shipping agents, he states that he has been commissioned to obtain suitable lodgings for a young gentleman who is about to arrive in London, and asks to be recommended to persons having furnished apartments to let. He then goes to the address given, takes the apartments, and in payment for rent in advance tenders a worthless cheque for a larger amount (usually written on plain paper), and receives the balance. His description is as follows: Age, about forty; height, 5 ft. 6 in.; pale face, hair and moustache dark brown, slim build, gentlemanly appearance, and of good address. The police hold a warrant for his arrest, and it is requested that he may be detained and handed over to a constable."

Dr. Jas. Olivier.—The paper is under consideration.

SICILY AS A HEALTH RESORT.

To the Editors of THE LANCET.

SIRS,—Medical practitioners are often consulted, and sometimes puzzled to answer their patient's question—"Where shall I go this winter?" Will you allow me to supply an answer that will suit very many valetudinarians? I am of that unhappy class myself, having inherited a cough from my father, and having been unceasingly troubled by my continuous barking. I have tried Algiers, and found it wet and windy; the Canary Islands and Madeira, and I have not a word to say about these lovely islands except that they are dull. I have tried other places with more or less success; but I never, in any part of the world, found a country that for health and amusement can equal Sicily. A patient should go to Palermo first—that is to say, in November and well on to Christmas; the climate then and there is perfect. After the middle of December he should go south, say, to Syracuse, a very warm place and the most historically interesting on this earth; and after a week among the remains of Greeks, Romans, Saracens, and Normans take the rail to Taormina. There is in that on-a-cliff-mountain town an hotel or pension kept by an English gentleman and his wife; an old thirteenth-century convent, with the far-famed Greek theatre behind the house, Saracen and Roman tombs in front, hoary-headed Etna at the side, and straight before one the Straits of Messina and the Calabrian Mountains. From his window one can see the rocks on which the sirens sat, the home of Circe, Scylla, and Charybdis, and below the site of Naxos, the earliest Greek colony. But, best of all, one can breathe. I have kept no record of the thermometer; but I can say that since I landed in Sicily, on Nov. 1st, I have only had a day and a half of wet weather. All else has been perpetual sunshine. The air is dry and warm; windows are always open. We sit out in the garden or on the balcony all day, and some of us on the latter under the stars till eleven at night. I have never anywhere experienced such a climate or such a place of perfect rest as the Pension Santa Catarina at Taormina, nor a place more abounding in botanical, geological, and archæological remains than this most magnificent spot on this historical island.

I am, Sirs, yours faithfully,

Castello, Catarina, Taormina. GEORGE PYCROFT.

THE TREATMENT OF POISONING BY NARCOTICS.

To the Editors of THE LANCET.

SIRS,—If this letter contains a new suggestion, and one worthy your columns, please admit it.

Would it be a new treatment, and worth trial, in cases of poisoning by opium, belladonna, or other narcotic, after the failure of ordinary remedies, to practise intravenous injection of normal saline solution, with a simultaneous or immediately prior venous bloodletting? It would seem to be a quick and safe means of washing out the tissues, and so lessening the actual and relative quantity of poison contained in them. From one to four pints of blood could be shed, and as much or a third more normal saline solution injected. If thought well, the method could be repeated after a fair interval; but I pass by detail. If it has not already been done, would it not be worth while to experiment in this direction on some of the lower animals (dog?) at one of our licensed laboratories?

I am, Sirs, your obedient servant,

Worcester, Jan. 25th, 1892. T. BATES.

AINHUM.

To the Editors of THE LANCET.

SIRS,—In your issue of Dec. 12th, 1891, in an article headed "Ainhum," referring to twenty cases of the disease treated by Mr. Von Winckler of British Guiana, I find you say, with regard to treatment, "this seems to resolve itself into removal." I merely write to say that about a year ago I treated a case of the kind successfully, and in a very short time, by dividing the skin and all the tissues down to the periosteum on the side opposite to the seat of the disease. The parts looked so very much as if they had been ligatured, that division of the internal ligature, whatever it might be, naturally suggested itself to me. I may mention that the patient had had the disease in the opposite foot some years previously, while residing at Barbados, and that the usual treatment had been adopted there (amputation), and that he really came to me for the purpose of getting the toe removed.

I am, Sirs, your obedient servant,

Trinidad, W.I. THOMAS MURRAY, G.M.O.

"AFRICAN FEVER."

Dr. Harford-Battersby, medical missionary on the Upper Niger, in an interesting communication which is too lengthy for publication *in extenso*, calls attention to the want of knowledge of African fever and the desirability of a thorough study being made of it. He says:—

"It may be urged that so much has been written about Indian fever that therefore we have no need of special study of African fever, but I believe that in many respects the malarial fever of Africa (which I have alluded to above under the title 'African Fever') is in many ways very different. For instance, one of the most fatal manifestations of malarial fever in West Africa in recent years (and curiously it has only been commonly noted in recent years) is the occurrence of hæmaturia or hæmoglobinuria in such a marked way that this is usually called 'Blackwater Fever.' I know several medical men besides myself who suffer from this form of fever. Surely we ought to get at some useful results by collecting evidence from all possible sources, so that we who may be called to work in these regions may have a scientific basis to work upon. It is not for me to dictate the lines that such an inquiry should take, but among other points the following questions seem to be important. 1. What forms of malarial fever do we find in tropical Africa, and what special symptoms or complications are generally met with? 2. What special localities or changes in climate seem to favour the production or development of the fever? 3. What do we know of the value of preventive measures, either hygienic or medicinal? 4. What evidence is there of the presence of a specific micro-organism, and does it correspond with the malarial bacillus which has already been described? Many other interesting points might be brought out by the inquiry, and perhaps some light might be thrown on some of the other specific fevers."

As far as we are aware, the only lectureship in tropical diseases in our British medical schools is held by Dr. Felkin of Edinburgh, who was formerly a medical missionary in East Africa. It is possible that this gentleman would be willing to assist in such an investigation as Dr. Harford-Battersby suggests.

MEDICAL REFORM.

To the Editors of THE LANCET.

SIRS,—The question of medical reform is in the air. It has been there for some time, and almost seems as if it cannot be brought down to earth, in spite of the efforts of various societies and individuals. If we are to have reforms, we must know exactly what we want, and I beg to suggest that a Charter should be drawn up embodying the necessary reforms, and then that the question should be brought to the front, and kept there, until our social and professional position has been gained; and it shall be taken for granted, even by the ignorant of the British public, that a doctor does not keep a shop for the sale of "bottles of stuff" more or less potent. The points of the Charter strike me somewhat as follows, but I write with reserve and subject to correction. 1. That our Council shall obtain increased powers to deal with matters affecting the general well-being of the profession, and that it shall represent the different sections as far as possible in proportion to their number. 2. That definite lines of policy shall be laid down with regard to charitable and provident work, and that no public work of this kind shall be undertaken by any member of the profession which does not comply with the conditions deemed fair and reasonable, both to medical men and the poor whom they desire to benefit. 3. That dispensing by medical men, except in case of emergency, be strictly prohibited where a chemist is accessible. 4. That the law against prescribing by chemists shall be strictly enforced, and that they shall not be allowed to supply any drug (with the exception of certain scheduled household remedies) without the prescription of a qualified medical man. 5. That the chemists' stores shall be periodically inspected to ascertain that their drugs are of good quality. 6. That all "patent medicines" shall be registered subject to a declaration of the active medical ingredients. If these lines of policy were followed the medical profession would become professional. *Advice* would be regarded as worth more than the medicinal compounds which form only one part of treatment, and medical skill would not, as now, be regarded by many good people as bounded superiorly by a cork, and in other directions by bottle. Provident associations can go on wherever they are desirable. Chemists will be glad to supply medicines for them at a nominal profit if they get more private dispensing. Public bodies will have to make arrangements for the supply of medicines for poor people. In many large towns they have already done so. Not only should we gain in time for diagnosis, but also in self-respect. While freely working for the poor in charitable or semi-charitable ways, we should insist on adequate payment from those who can command everything but medical attendance at ordinary rates, but who prefer to take advantage of low and disreputable contracts.

I am, Sirs, your obedient servant,

Loughborough, Jan 2nd, 1892. J. B. PIKE.

CARPENTER AND DUKES FUND.

To the Editors of THE LANCET.

SIRS,—Please insert the following additional subscriptions to the above fund in your next issue, and oblige yours faithfully,

RESTRICTIONS ON PRACTICE IN CANADA.

L.R.C.P. Lond. & M.R.C.S.—The readers of THE LANCET have already been put in possession of the change made by the province of Ontario, which requires gentlemen wishing to practise in that province to pass an examination, even though they may be qualified and registered in Great Britain. As some of the Colonial Legislatures, as well as those of the United States, are inclined to make changes restricting medical practice to their own graduates, it is unwise for gentlemen to go out meaning to practise without making inquiries from official sources as to the exact state of the law at the time.

A Physician.—The conjoint qualification does not entitle its holder to put "Dr." on his card.

COMMUNICATIONS, LETTERS, &c., have been received from—Dr. Atkins, co. Cork; Dr. Appleton, London; Mr. Alderson, London; Mr. Anderson, London; Mr. Blackett, London; Mr. Birchall, Liverpool; Mr. Lennox Browne, London; Mr. Bridgman, Taormina; Mr. C. F. The Harveian Lectures

ON

COMMON NEUROSES, OR THE NEUROTIC ELEMENT IN DISEASE AND ITS RATIONAL TREATMENT.

Delivered before the Harveian Society of London, Nov. 19th and 26th and Dec. 2nd, 1891.

BY JAMES F. GOODHART, M.D., F.R.C.P.,
PHYSICIAN TO GUY'S HOSPITAL.

LECTURE III.

WE must now pass from the neuroses of the heart and lungs to take up those that show themselves in the abdominal viscera, and there are several that supply much interesting material bearing on their rational treatment. I shall take in order the stomach, the intestine, the kidney, and the liver. I have much to say about the stomach and the rational treatment of its diseases, for I believe they are often treated most irrationally; and let me take first the common, very common, ailment of flatulent dyspepsia. And here at once I suspect that if anyone who has devoted himself to the treatment of stomachs thinks me worthy of any attention, he will at once fall foul of me when he finds that I am going to have my say on this subject in *general*, so to speak. "What can he know about dyspepsia when he talks of it as an entity that knows no differences of form?" Well, I have often said that although there are all sorts of different dyspepsias elaborated out of the heads of individuals, if I were going to write a book on indigestion, I should first devote myself to a volume on diseases of the nervous system. Surely I cannot be wrong when I make this statement, that of the numbers of dyspeptics that fill the doctors' lists the greater proportion by far are neurotics in one form or another. It is really no great exaggeration to say that there are only two forms of indigestion: that produced by over-eating and drinking, and that due to a failure of nervous power. There are other conditions that are met with as rarities, but these who knows anything about? For instance, there is an acute condition originating in some indiscretion in diet, in which the stomach takes to forming sulphuretted hydrogen. I have seen three or four such cases, but if I try to find out anything about it the authorities have very little indeed to tell. Then we talk about acid dyspepsia and atonic dyspepsia, as if any dyspepsia were other than acid, and, from my point of view, as if atonic dyspepsia were necessarily something different. Gouty dyspepsia is another term in frequent use, but it is no different; it is often enough a little of both the others, and sometimes the indigestion of over-eating and over-drinking as well. Nor is the classification, according to morbid anatomy, much better, for here the observer talks of catarrh of the stomach as if the stomach easily catarrhed; whereas we know as certainly as we know any fact of physiology or medicine that of all the multitudinous sins of commission that are done to its would-be detriment there is happily not one in a hundred, if so many, to which the stomach deems it necessary to turn a hair. Were it otherwise the human race would not last out two or three generations. No! If there is one thing that is certain, it is that the stomach is an organ that has been trained by centuries of custom, and by slow processes of evolution, to a condition of hardihood that endows it with the special attribute of comparative callousness, and within limits, and *mutatis mutandis*, I would as soon talk of catarrh of a bird's gizzard. But if, as is assuredly the case, the stomach will stand all this hard work, and still come up smiling, it must needs be supplied with an amount of "go"—in other words, of nervous energy—to enable it to do its work; and it is just this supply that, in this era of high civilisation, is often and often cut short. There is a sort of action abroad that would seem to say: "Oh! anything is good enough for the stomach." Men go into the City, for example, and, beginning at 9 A.M., go on till 6 or 7 P.M., and often enough bring home their business worries with them, their brains being all the while in a state of turmoil. In the midst of this they eat and drink, and ask their stomachs to digest. But if they have exhausted their nervous supplies—and more than exhausted, have overdrawn their capital of this, as they often have to no inconsiderable extent,—where is the stomach to get its motive power? Take, again, the neurotic woman, in any of the many forms in which she presents herself to your gaze. No lecturer, gifted even with the most consummate art of word painting, could depict the many ways in which women of this sort consume their nervous energies; but consume them they certainly do, and they constantly find themselves in the same case, and their stomachs find themselves called upon to perform the impossible task of making bricks without straw.

I assert without any fear of contradiction that this is *the* indigestion of the present day. How do we treat it, and what is its rational treatment? Well, I suppose, it is ten to one in favour of the patient getting a little soda and bismuth, and perhaps a little gentian or calumba in addition. If the patient will run to it, he may take some rhubarb and magnesia instead, and generally, I believe, it must be said that he at first leaves his doctor's door well satisfied that he has got his money's worth. But time goes on, he has consumed his appointed potions (most of these people take medicines well), and he does not feel any very sensible relief from the vagaries of stomach discomfort to which he has been subjected: so back he goes to the doctor, and now probably a few drops of mineral acid and nux vomica are ordered, and this time it is precisely prescribed, perhaps, to be taken an hour before meals, because—well, because—well, I will leave that to the Seers. But time again goes along, and our dyspeptic begins to have qualms whether he is placing his money rightly, and before long he is to be found at somebody else's door, and No. 2 has *his* turn; and so on to Nos. 3 and 4, up to the 12th. If the patient, male or female, be a particularly bad case, he or she will produce in the course of consultation with, say, the tenth best physician on stomachs that exist in the metropolis, a bundle of prescriptions that for thickness may well make his face turn pale and his eye involuntarily seek the clock, while his ears will tingle, I think, with shame that any human being can be so bereft of common sense as not to have got his cure or let it alone ere it has come to this. Will anyone say this is an overdrawn picture? I have seen it too commonly not to know. There are two things that I very generally do on such occasions: one is to indulge in a very short-lived regret that I entered the medical profession, and the other to ask the patient to have so valuable a manuscript bound in calf. But why do things come to this pass? Are we only to have a laugh at the ignorance of the uninstructed? Is there no beam in our own eye? I think there is a very big beam. And it is this, that we are much too fond of giving a prescription because the uninstructed want it, and we do not ask ourselves the question, Is a *drug* the right treatment here? Will it ever come to pass that the public will pay us for our brains, and receive an order for physic as an evil, which, if it must be, must be? But I am wandering from my subject. I do not wish to convey that in these cases of indigestion we can do without drugs, but I do mean to convey most urgently that they are not *the* treatment. It does not follow because a man or a woman has dyspepsia that bismuth and soda are forthwith to be shot into his or her stomach. The great majority of the dyspeptics of the present day are so because their nervous power has run down, or has been incontinently consumed in other directions, without any regard for the needs of the stomach. The first and foremost treatment in these cases is to take what steps can be taken to lessen the tax upon the nervous centres, and to tone up those that are run down. Often would I, were it not a mockery, write on the prescription paper of many a hard-worked man in the City toiling for his bread-and-cheese: Recipe—£500 a year and an eight-hour day. Often and often, for the woman who frets her nerve force into useless fritters, "An occupation that shall give you freedom from yourself." Could one but give these things away there would be no occupation for us in the way of treating indigestion, and it is the hardest part of a doctor's life to feel what he knows to be the right treatment, and yet to be obliged to give a dose of medicine as the nearest approach to the possible. But such *is* our life, and we cannot do otherwise than accept its conditions; but in doing so it falls to me to say that these are cases for tonics and every available means

Digitized by Google

for invigorating the nervous system, and the remedies I have decried, but have in no way besmirched—for they are good enough in their place—are to come in their proper place, and be only called to our aid to treat symptoms of passing occurrence.

Next, though not quite in order on my list, I will take anorexia, or want of appetite, because it is closely bound up with this subject of indigestion. There is no more common ailment than this, and it is much more common amongst women than amongst men, although it may be found in either sex, and it also is largely the product of our civilisation, and of an improper consumption, or feeble supplies, of nervous energy. Therefore I think the term proposed by the late Sir William Gull of anorexia nervosa a very fitting one. But the cases recorded by that distinguished physician were all cases of extraordinary severity, and it will be in the recollection of some here that such as were narrated in the Clinical Society's Transactions, and by others now and again afterwards in the medical periodicals, have all been remarkable for being in the last stage of emaciation. Interesting as these cases are, they are certainly rare, and I want to extend the term to a much commoner class of cases. I think there can be no doubt that the same disease exactly, but not reaching anything like the same extent, may be seen almost daily by anyone who chooses to see it in his own practice. I read in one of the daily papers the other day this paragraph: "Almost the only failing of the Englishwoman is that she has no touch of gluttony. She does not take an intelligent interest in what she eats. Anything will do, she says. She is incapable of appreciating good cookery, and that is one of the reasons why the English cuisine is fraught with so many terrors." I shall express no opinion about the truth of the latter clause, but I am sure about that of the first. There are hundreds, ay thousands, of women going about who habitually have the smallest of appetites, and they are often enough women of a very active habit of body and brain. Now we all reason from our own experience far more than we do from what we get secondhand. And the familiar experience of everyone here is that when we have gone long without food we soon reach a stage in which we do not care whether we have food or not, and we may easily under such circumstances reject such food as we put into our stomachs. Apply this to the case before us. An individual starts from whatever cause, for the minute it is not necessary to inquire, with a small appetite; she gets tired or overdone, as is very easily accomplished, on the small amount of food that is taken. Meal time comes on, and she finds herself without appetite, and thinking, as most people do, that if the appetite be not there the food cannot be necessary, none is taken, or the meal becomes smaller than the one preceding. So the case goes on, and little by little no food worth the name is taken. Let me give you the day's record of one or two of these cases. A small part of an egg and a finger of toast and a cup of tea for breakfast (this is rather a respectable meal for a case of this kind); for lunch a drachm or so of veal cutlet, no vegetable, or bread or pudding; a cup of arrowroot and brandy at bedtime. A second case: for breakfast, a little potted meat and dried up bread, a cup of strong tea with very little milk; a very small slice of meat and a little vegetable and milk pudding or stewed fruit for dinner; a cup of strong tea, dried up bread, or a biscuit and fruit for tea; milk pudding and a biscuit for supper, and a little soda water at bedtime, and so on.

Now these cases are really very interesting as showing upon how very little life can be sustained; and, indeed, not only sustained, but made to do quite a large amount of active work. Now what happens, what must happen to the stomach under such circumstances? It does not need much labouring; your own common sense will say at once that the stomach, gradually accustomed to diminishing meals, gradually shrinks, and becomes inactive; and inasmuch as the bodily vigour runs at a gradually lessening tide, so it has less and less vigour, until it goes almost to sleep. There are discomforts attending the course of these cases that hasten the process. Their friends notice how little is taken, and all sorts of things are advised and made trial of; and these spasmodic efforts cause to the languid stomach a good deal of pain. The patient then argues within herself that something taken at the last meal has disagreed, and it is cut for ever out of the diet list. Another attempt is made with something else, but with no better success, and out goes this also. Nor does she stop here. So by slow degrees the possibles of her digestion become more and more attenuated. This is nothing more than the common history, not of rare cases, but of any number. What is the use of treating these people only by bismuth and soda and all the usual stomachics? Granted that they have pain, what is the pain due to? It is the result of the state of disuse into which the stomach has fallen and to the irritable state of the nerves which the generally depressed state of body has engendered. The proper method of cure is to first explain to the patient what has happened as the result of the process of gradual starvation, what is the condition and size even to which their digestive apparatus has shrunk; and they must fully understand that it is impossible, or at the least unlikely, that they can be restored to their former selves without a certain amount of discomfort, not to say pain—that their stomachs need to be educated back to a healthy habit, and to be stretched to a more natural size. These, therefore, are the cases, or one class of them, that undoubtedly derive great benefit from what is now generally called Weir-Mitchell's treatment—of stuffing and massage. And it is a treatment that in most cases does these people a great deal of good. They gain weight and are altogether different creatures. I said just now that we might dismiss for the minute the initial fault in these cases; but I have now to say that they are neurotics, almost all of them, and, what is more, they are neurotics of a rather bad type. By this I mean that, although they are submitted to treatment of this kind, and derive much benefit from it, they are exceedingly likely to get back to their old habit again, after a longer or shorter time, and some of them find their way ultimately into the ranks of the insane. This is the fundamental cause, but there is another condition that has, I believe, to share a good deal of the blame. I allude to the most pernicious practice of taking no breakfast. Small eaters, with their last meal taken at seven or half-past in the evening, and probably all digested, so little has it been, many, many hours before morning dawns, and the day's work is then begun on a finger of toast and a cup of tea—sometimes, I have been told, in the exceptionally perverse without even any milk in it. And this to last them till past middle day. How can anyone be expected to have any vigour of mind or body under such circumstances? But I daresay someone will be thinking that the no-breakfast plan is such a common thing that I need not make such a fuss over it. I would not do so if the meal time alone were changed. There is no objection that I know to the chief meals being taken at, say, twelve and six, on the foreign plan, but then the two meals are *taken*, not sniffed at. But I confess to thinking so highly of our English plan of starting with a good solid meal, that a cup of tea at half past seven in the morning, although very nice, is, from a digestive point of view, a mistake, and if I belonged to the band of medical advisers to insurance societies, although I think I should pass many a heart that is now looked at askance, I doubt if anyone would get in as a first class life under my *régime* unless he produced evidence that the volume of his breakfast came within measurable distance of

> "Devilled kidneys and sweetbreads and ducks and green peas,
> Baked sucking-pig, goose, and all viands like these."

It is food, and not medicine, that is the prime need of these people; but I think that it may well be doubted whether this is put before them with all the blunt uncompromisingness and persistency that the occasion and their blindness in the matter require.

Neurotic vomiting is another branch of the same subject, but I shall not discuss it, because it is so well recognised that it rarely fails to receive the appropriate treatment. There is, however, a group of cases in children of which I do not think much is known, so I shall deal with it a little more in detail. I allude to the sudden periodical paroxysmal vomiting of extreme violence that is occasionally seen in children of four, five, and six years or so of age. It goes on for twenty-four, thirty-six, or forty-eight hours; everything, often even water, is returned. The child becomes hollow-eyed and choleraic in appearance, and is, indeed, brought to the very verge of death. In a first attack of this kind it is not unnaturally supposed to be due to some error of diet, although it puzzles the parents often to say what that error may have been. It is, of course, an attack that may very well be set up by an irritant poison in the shape of food, but in these cases the irritant is for the most part

Digitized by Google

trivial, and similar attacks tend to recur over and over again in the same child. Moreover, they always lead to the most rigid dieting, and yet the attacks recur. I have notes of six or eight such cases, and I cannot but think that the vomiting is of cerebral origin, and not gastritic. At any rate, I do not think such cases should be treated by a too strict diet, for by such means the youthful stomach fails to obtain the requisite amount of experience, and in consequence hereafter takes fright at such trivialities as one currant in a bun. I believe that bromide of potassium and moderate care in diet are more successful. Another common form of neurotic dyspepsia is the condition that is known as *flatulence* simply, and how closely this condition goes with debilitated states of the nervous system is well illustrated by the following case: A man of forty-two, who voluntarily called himself "a wretched nervous fellow," had been dyspeptic for many years, and this makes his heart irritable. His wife died a few months ago, and he got into a very low state. He went to the seaside for seven or eight weeks, and got better; but as soon as he came home again he relapsed. His attacks are very peculiar, in that they always commence with *sleeplessness*, and when this begins he always knows that in three or four days he will be attacked by flatulence and dyspepsia. Having mentioned this man, let me tell of another condition, also in the male, because there seems to be some difference between male and female in this respect. It would almost seem that the flatulence of the male sex is chiefly in their stomachs, and that of women in the bowel. This second case was in a highly neurotic man, who had taken himself out of an honourable calling into that of speculative finance and Monte Carlo-ism. This man came into my room one day, and treated me to the most extraordinary musical performance—his stomach being the bellows, and his mouth the pipe—that I ever remember to have heard. The only advice I deemed it necessary to give him was the very simple command to stop it. And I hope it cured him; for bar his stomach, which was a little mad, he seemed sensible enough.

Now here, again, it often enough happens that such are treated as cases of indigestion, and drugs are put into their stomachs as the be-all and end-all of treatment, and they are never told about the mechanism of the flatulent distension; and the consequence is that, feeling distended, they dispose of their surplus gas by eructation and are easy for a time. But in so doing they become gas factories; soon more is secreted, and that is passed off, and so on, and the stomach is enticed to produce more each time—the demand, according to the universal rule, creating the supply. If, on the other hand, you tell them that each return of momentary ease is accentuating a habit and really making them worse, and that if they bear with what, after all, is but a slight and passing discomfort, they will soon be better; and then apply such remedies as the case seems to call for, it will take no time to cure the majority of cases. It will not be so easy with a minority. These betoken the intensity of their neurotic degradation, first by the dismal setting of their visage, and then by the minute and exaggerated description of their woes. For these it is hard to say what treatment will suffice.

In addition to these cases, or such as these, there is a far larger class of dyspeptics who come complaining of a troublesome distension after their food, and who, looking upon it as a symptom of indigestion, and due—for this is the common corollary—to something they have eaten, they diet themselves and, meeting with no great measure of success, they apply to us. The old tale of drugs is gone through, and they are dieted and given some pepsine in one form or another. But often enough they are not cured in this way, and, what is more, they will be fortunate if they ever are. Again, I appeal to the experience of anyone here. Who has not felt the same discomfort, more or less, when overworked or harassed in one of the hundred ways that happen to man in this world of everyone for himself? And when you have felt this condition what have you thought of it, and did you take bismuth, or what did you do? Was not this rather the outcome of your deliberations, "Such and such cases have taken it out of me"; or, "I have been busy lately, and had too little time for meals." And to those of us to whom this condition is no uncommon thing, have we not rather thought much in the strain to which I have already given vent, that in these days of hurry-scurry our brains run ahead and take no thought for the stomach, and that in consequence there is almost a necessity for many of us to suffer from a slow digestion; and a slow digestion means that, as regards symptoms, there will be more or less distension after food, sometimes after breakfast, in others after one of the later meals of the day. But taken patiently and not thought about, it all passes off after an hour or two. If we have been wise, we have not done much in the way of medicine; we have, perhaps, taken a little strychnia and phosphoric acid; we have not made much alteration in our diet, which has been plain and wholesome before, but we have taken a little more pains with it, and put food under cover more tenderly, and, perhaps, as a temporary thing, we have added a little pepsine to the meal. No mystery in all this. We have treated ourselves on plain common sense principles. Do we always treat our patients to the same approved methods as we deem fitting for ourselves?

(To be concluded.)

The Lettsomian Lectures

ON THE

SURGICAL TREATMENT OF TRIGEMINAL NEURALGIA.

BY WILLIAM ROSE, F.R.C.S.,

JOINT PROFESSOR OF SURGERY IN KING'S COLLEGE, AND SURGEON TO KING'S COLLEGE HOSPITAL.

LECTURE III.

THE GASSERIAN GANGLION AND ITS REMOVAL.

MR. PRESIDENT AND GENTLEMEN,—In my previous two lectures I have traced the history and gradual development of the surgical treatment of trigeminal neuralgia, clearly indicating the tendency amongst surgeons in this and other countries to substitute more central and radical measures for less effectual peripheral treatment. For however great the relief may be for a time after neurectomy, or combined neurectomy and nerve-stretching, a recurrence of the painful symptoms is unfortunately the rule rather than the exception. In a few months, or perhaps at the end of a year, these patients apply for further treatment, and in many instances are willing to undergo any risk from an operation that holds out the slightest prospect of alleviating their sufferings. They have told me that life under such circumstances is unendurable, and have even threatened self-destruction when the paroxyms have been extremely severe, reason itself being endangered; whilst others have expressed the hope that they might never regain consciousness from the anæsthetic administered at the operation, rather than again experience such exquisite agony. It was a case of this desperate character that first stimulated me to make an attempt to reach and remove the Gasserian ganglion, and after frequent conversations with Dr. Ferrier, and a careful study of the anatomical relations of the ganglion to the base of the skull, I was convinced not only of the possibility but also of the practicability of this proceeding. The results, more or less favourable, following the removal of Meckel's ganglion also acted as a powerful argument in favour of producing a still more satisfactory effect if the Gasserian could be reached and isolated from the brain, even if the whole ganglionic mass could not be excised.

The Gasserian or semilunar ganglion is a small mass of greyish-yellow nerve substance, forming an expansion upon the larger or sensory root of the trigeminal nerve; into it the motor root does not enter, and thus it is analogous to the ganglion upon the posterior roots of the spinal nerves. The trunk of the fifth nerve issues from the pons as a cord flattened horizontally, which passes through an opening in the dura mater to reach the apex of the petrous portion of the temporal bone where the ganglion is lodged. This opening is placed just behind the posterior clinoid process in the anterior attachment of the tentorium, and has the superior and inferior petrosal sinuses respectively above and below it. The space in which the ganglion is located is known as the Cavum Meckelii, and corresponds exactly to the depression at the apex of the petrous bone. It is essentially an extra-dural space, a matter of considerable importance in any operative interference with it. Some French anatomists, however, state that the space is lined

Digitized by Google

below by a thin reflection of the dura mater, and thus the ganglion really lies encapsuled within the dura; I have, however, experienced no difficulty in any of my cases from this lamella of fibrous tissue. In shape the ganglion is crescentic, or somewhat like a haricot bean flattened out, with the convexity forwards. The two chief surfaces are directed respectively forwards, outwards, and a little upwards, and backwards, inwards, and downwards. The antero-external surface is in somewhat close relation with the dura mater, from which it is not altogether easy to separate it; the postero-internal surface lies on the bone, a thin layer of dura acting as periosteum intervening, and with this it is very loosely connected. The trunk of the fifth nerve enters its postero-superior border at a point corresponding to the hilum, and at the antero-inferior border are given off the three main divisions. The anterior portion is prolonged into the ophthalmic division, which is very closely connected with the dura mater forming the outer wall of the cavernous sinus, and it is a question whether the removal of this portion is possible without laceration of the sinus. Thiersch and Horsley both emphatically contend that the detachment of this portion is impossible, but recent investigations have shown me that on the cadaver at least it can be accomplished, though not without some difficulty. The internal carotid artery, passing upwards in its canal in the petrous bone, lies first below and then internal to the ganglion, previous to gaining its position by the side of the posterior clinoid process in the floor of the cavernous sinus.

The various methods which have been suggested and practised of reaching the ganglion must now be considered. Up to the present this has been accomplished in three different ways, viz.: (1) By Mr. Horsley's intra-cranial operation; (2) by ablation of the superior maxilla and trephining the base of the skull; and (3) by trephining the base of the skull through the pterygoid region, the method which I have adopted in my last four cases. Mr. Horsley is in error when he stated in his paper[1] that I performed the Pancoast-Salzer operation, for, as described in my last lecture, Salzer's method consists in turning down the zygoma, masseter, and temporal *en bloc* by a curved incision, practically perpendicular to the varying directions of the fibres of the temporal muscle. My operation is really an elaboration of Krönlein's[2] modification of Pancoast's original proceeding, except that I make a different skin flap. I have recently received an interesting communication from Professor Andrewes[3] of Chicago, who during the last twelve months has been making investigations on the cadaver as to the best means of reaching the ganglion. He has also sent me details of two cases in which he has followed out my suggestions in his operation, and to which I shall presently refer. His studies have led him to much the same conclusions as to the best and most direct means of effecting this as those at which I have myself arrived. He suggests six different routes; but, inasmuch as two of them are essentially very slight modifications of my own plan, they may, for practical purposes, be reduced to four—the three mentioned above and a fourth, which, however, is only suggested as possible on the cadaver, and is at once condemned by the author himself.

1. With regard to the *intra-cranial operation*, Mr. Horsley has so recently published his views on this subject, and his method of operating, that a detailed description here will be unnecessary; but, briefly, it consists in the exposure of the squamous portion of the temporal bone by turning down a large temporal flap and in the removal of the whole of the exposed portion by means of a trephine and bone forceps. The dura mater is then freely divided along the whole length of this opening, and the temporo-sphenoidal lobe laid bare. "A broad copper retractor with smooth and everted edges is then gently slipped underneath the lobe, and slowly but steadily raised. The lobe is partly moulded, partly lifted upwards, and the floor of the skull is then seen and illuminated by the electric light." The edge of the tentorium is looked for, and the position of the root of the nerve as it emerges from the brain ascertained. The ganglion will not be visible at first, being covered by the dura, but an incision is made at the point where he considers it should be, and by enlarging this the nerve root is stated to be seen with ease, "freely lying in the little canal," to use his own words, and can then be divided and the ganglion removed. The first case Mr. Horsley treated in this way proved fatal in seven hours from shock, and as far as I can make out from the scanty information given in his table of results he had not, when his paper was written, attempted a similar operation again, though in two cases an intra-cranial division of the nerves was undertaken, the exact details of which are not stated, but in neither of these was the ganglion dealt with. An examination of the inside of the base of the skull from which the brain has been recently removed is sufficient to convince one of the difficulties which must be experienced in attacking the ganglion from above; much more so is this the case with the brain *in situ*. Again, when we consider that the ganglion is situated practically outside the dura mater, it seems an unnecessary increase in the severity of the operation to open this investment in two different situations; and, however delicately we may handle the temporo-sphenoidal lobe, it can do it no good to compress and mould it by retractors to a sufficient extent to enable the base of the skull to be clearly seen and the necessary manipulations undertaken. Moreover, Mr. Horsley himself admits that the existence of several small veins passing from the temporo-sphenoidal lobe to the superior petrosal sinus must necessarily be ruptured in this proceeding, and so give rise to troublesome haemorrhage, and I cannot imagine that the superior petrosal sinus itself can escape if an incision be made in the direction indicated. Bleeding in this locality is difficult to arrest; and even if not absolutely dangerous to the patient from its extent, it may become so by its pressure effects. Again, the extensive removal of cranial bone must be a source of subsequent risk to the patient, and the disfigurement of the face from the large temporal flap is very marked compared with the insignificant cicatrix resulting from my own procedure. These latter points, however, would be of little importance if certain relief could be given to the painful condition without danger to life. From these considerations one cannot resist the conclusion that this method of reaching the ganglion is scarcely justifiable in the light of present experience, and that if the ganglion can be satisfactorily reached and dealt with along some safer route it is far better to avoid the risks certainly associated with an extensive intra-cranial operation.

2. My own efforts hitherto have been entirely directed to reaching the ganglion through the base of the skull, and at present, after an experience of five cases, I see no reason for altering my views. In the first case, one condition on which I was allowed to operate was that I should remove what was thought by the patient to be the seat of the greatest pain—viz., the right superior maxilla; under no other circumstances should I have undertaken such a disfiguring plan of treatment. The operation of ablation of the superior maxilla was performed in the usual way without any difficulty, and, as generally happens, the pterygoid processes broke off close to their base. This gave me plenty of room to expose the foramen ovale, and the trephine was easily applied in a direction upwards and a little backwards. After the removal of the disc of bone containing the foramen as its centre, the ganglion could be easily seen, both by myself and my assistants, by the aid of the electric illuminator, without which manipulations at such a depth would be impossible. At that time I was not provided with the special hooks I have used in my later cases, and so I picked the ganglion away piecemeal with a pair of fine hooked forceps. The wound was of course one communicating with the mouth, and consequently its asepticity could not be maintained. This condition may account in part for the loss of the eye, but with this exception the patient made an excellent recovery. I regret that I did not take proper precautions to render the conjunctival sac aseptic before the operation, or to protect the eye subsequently. It is possible, moreover, that a drop or two of chloroform may have fallen into and irritated it, as the patient was somewhat restless. Be that as it may, subsequent experience would tend to prove that, unless the strictest precautions be taken for the protection of the eye at the time of the operation and for weeks after, the disturbance of the trophic centres may lead to degenerative changes entailing the loss of the organ. But even if the eye should unfortunately be lost, the immunity from pain more than compensates for this.

3. I now turn to my present plan of operating through the pterygoid region, which must be described in detail. The patient is carefully prepared in order to be in as favour-

able a condition as possible. The bowels are moved by a mild purgative given the night before. The face is washed as thoroughly as the patient will permit with soap and carbolic solution (1 in 20) some hours before, and an antiseptic dressing applied. This is an important matter, seeing that (as I have previously remarked) the skin is often very dirty on account of the pain caused by any attempts at washing. Chloroform is perhaps the most convenient anæsthetic to employ, and when the patient is fully under its influence the skin should be again thoroughly washed, the external ear cleansed, and a plug of salicylic or some antiseptic wool inserted into the meatus. The conjunctival sac must also be thoroughly washed out with an efficient but unirritating antiseptic, a 1 in 2000 solution of corrosive sublimate being perhaps the most satisfactory; during this proceeding the lacrymal sac should be squeezed, as often collections of mucus are found therein, and regurgitation of these through the canaliculi will again cause septic contamination of the conjunctiva. In order to ensure closure and protection of the eye, both during the operation and for some days after, two fine horsehair or catgut sutures are introduced through the integument of the upper and lower lids, about 2 mms. from the palpebral margin of either lid, and exactly opposite each other, taking up small folds of the lax skin, which are approximated by tying the sutures. The operation itself may be divided into six stages, as follows:—1. Incision through skin and reflection of flap. 2. Section of zygoma and coronoid processes, and detachment of masseter and temporal muscles. 3. Exposure of the base of the skull, and search for the foramen ovale. 4. Opening the base of the skull. 5. Removal of ganglion. 6. Reposition of displaced structures and closure of wound.

First stage.—The skin incision (Fig. 1) is made by entering the knife over the malar bone about half an inch below the external angular process of the frontal, and carrying it along the zygoma and down in front of the ear over the parotid region to the angle of the jaw, and then forwards along the lower border of the horizontal ramus as far as the facial artery. This done, a flap can now be dissected forwards, consisting of skin and subcutaneous fat only, care being taken not to injure Stenson's duct or any of the branches of the facial nerve which lie in close contiguity to the masseteric fascia. Before this is completed, either a fine catgut thread can be inserted in either side to form a landmark in the subsequent suturing of the wound, or a crosscut can be made in the skin. The scar resulting from this incision can be rendered almost imperceptible if great care be taken in stitching the parts together and accurately matching them up. Many other incisions have been devised for similar operations in this neighbourhood, but I do not consider them so satisfactory. Krönlein used an incision which was practically H-shaped, the transverse line being placed over the zygoma. Pancoast operated through vertical incisions placed along the anterior and posterior borders of the masseter muscle and joined by a transverse cut along the zygoma. The great objection to these is the anterior vertical incision, which is very disfiguring and of doubtful utility. It is perfectly feasible to dissect up a skin flap in the face without encroaching on the nerves, and I would contend that the curved incision, whilst it gives a maximum of space with a minimum of disfigurement, will in no way interfere with the subsequent mobility of the facial muscles. The skin flap must be carefully protected by a few layers of purified gauze during the operation, and not unnecessarily handled or exposed to pressure or rough manipulation. It is better to avoid retractors in order to hold it out of the way, and its temporary fixation by a catgut suture to the upper part of the chin will be found beneficial. The anæsthetist must prevent any chloroform dropping on the under surface of the flap, and if he be using a towel he must not allow the corner charged with moisture to touch it. Particular stress is laid upon these details, as it is most important not only to maintain asepsis and obtain primary union, but also to leave as little trace of the surgeon's work as possible. After raising the flap any arterial hæmorrhage of importance should be controlled by Spencer Wells' forceps, and probably the transverse facial vessels will need ligature.

FIG. 1.

Sketch from dissected subject, showing stages of operation. The zygoma and masseter are turned downwards and backwards; the coronoid and temporal upwards; the great wing of the sphenoid exposed by detachment of external pterygoid, showing relative position of foramen ovale and trephine track. (For clearness' sake the two latter are purposely placed a little forward.)

Digitized by Google

Second stage.—The zygoma (Fig. 2) is now cut down upon by an incision along its course, and laid bare by means of suitable raspatories and periosteum detachers. Two holes are drilled at the root of the zygoma, and two also anteriorly through the zygomatic process of the malar line. This is best accomplished by a fine drill driven by a dynamo. The drill used should be of such a size that the perforation in the bone may carry wire of gauge No. 22, and the holes should be about one-third of an inch apart. The bone is then divided between them by a fine saw, and in such a way that the anterior saw-cut is directed obliquely downwards and forwards, the posterior part of the zygoma being divided as near its root as possible. It is obvious that the bone can be drilled much more efficiently whilst the zygomatic arch is intact; it can then be subsequently replaced without difficulty, and maintained in position by means of silver wire. The zygoma thus detached is displaced downwards and backwards together with the masseter; to facilitate this it will be necessary to divide the muscular fibres attached anteriorly to the malar bone. Necrosis of the zygoma has occurred in some instances where it has been detached and turned down by this plan of treatment; but I cannot help thinking that such has been due either to a septic contamination of the wound or to some rough handling of the bone which might have been avoided. Great care must be taken not to interfere with the attachment of the fibres of the masseter

FIG. 2.

muscle to its under surface, from which its nutrition is derived—and in all probability the wiring of the bone into position after preliminary drilling is another preventive of necrosis, for in none of my own cases have I had the slightest trouble or subsequent difficulty. When the masseter has been drawn downwards and backwards as far as possible, consistent with the integrity of the important adjacent structures, and a little cellular tissue picked away, the coronoid process will be exposed, together with the tendon of the temporal muscle, which, it must be remembered, passes lower down on the inner aspect of the bone than on the outer. In Cases 2, 3, and 4 this process was drilled to provide holes for subsequent wiring, and then sawn off obliquely downwards and forwards. The detached bone was turned up with the temporal muscle, and the deep fibres encroaching upon the ramus of the jaw required careful division. But latterly I have begun to doubt very much the advisability of attempting to gain osseous union of this process; for the temporal muscle attached to it is paralysed by the operation and necessarily atrophies, with the result that very considerable impairment of the mobility of the jaw ensues. In my last case, therefore, I simply divided the coronoid without attempting to drill it, and drew it and the muscle upwards out of the way, subsequently excising it and a portion of the temporal tendon.

Third stage: Search for the foramen ovale.—A certain amount of loose cellular tissue and fat will now present, under which will be found the external pterygoid muscle, running transversely backwards, to be inserted into the condyle of the jaw; and perhaps below it a small portion of the internal pterygoid may be seen. Running superficially across the former muscle, between it and the jaw, the internal maxillary artery is usually found, which passes into the spheno-maxillary fossa by dipping between the heads of the muscle. The artery, if it has not been tied at a previous operation, should now be sought for, and divided between a double ligature; by this means hæmorrhage, which might be troublesome during the later steps of the operation, will be avoided. The inferior dental and gustatory nerves under normal circumstances pass downwards from under the lower border of the external pterygoid muscle; but if they have been previously removed, their assistance in guiding the surgeon to the foramen ovale is not available. The external pterygoid muscle is next detached from the great wing of the sphenoid

FIG. 3.

and from the outer surface of the external pterygoid plate, by scraping it off the bone with suitable raspatories; it is of course pushing it downwards. The knife should be used as sparingly as possible, and the strands of muscular tissue are best picked and cut away with dissecting forceps and a fine pair of blunt-pointed scissors. By this means the under surface of the great wing of the sphenoid is exposed, and the outer pterygoid plate. The foramen ovale is now to be brought into view, a matter often of some difficulty, and the occasional reference to a dry skull held by an assistant will be a considerable help in indicating its position in relation to the neighbouring landmarks. (Fig. 3) It is usually on a level with the eminentia articularis, but occasionally lies a little behind it. In fact, the portion of bone which one first reaches in this deep part of the operation is well in front of the foramen, and one is apt to get too far forwards,

Digitized by Google

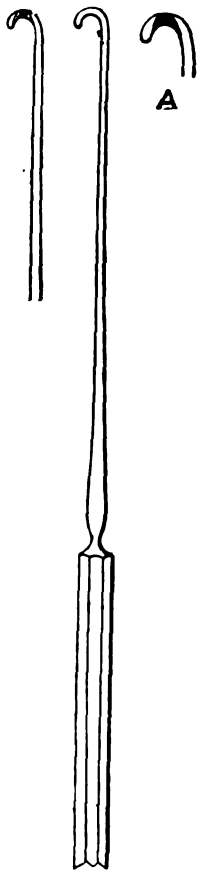
so that the pterygo-maxillary fissure is mistaken for it. In the third of my cases this actually occurred, and at first I trephined the sides of the fissure, not discovering my mistake until I found orbital fat protruding from the opening. The relation to the root of the pterygoid processes is another guide; the foramen lies usually a little behind and external to the base of the outer plate, but sometimes directly behind it. The position, however, is not constant, and Mr. Carless has found the greatest variety in the skulls which he has examined for me. "The base of the external pterygoid plate," he states, "is by no means a fixed guide, in that in many old skulls there is a formation of bone (like a tongue) projecting backwards towards the spine of the sphenoid, usually external to the foramen ovale, and deeply channelled or grooved for the middle meningeal artery." M. Testût[4] also mentions this fact, stating that it is due to an ossification of the pterygo-spinous ligament of Civinini. The sphenoidal spine lies immediately behind the foramen ovale and about a centimetre from it, the foramen spinosum intervening and placed about 2 mms. behind the oval opening; the spine cannot, however, always be felt on the living subject on account of the depth of the wound and the limited space in which one is working. Under these circumstances it is important to define clearly with the finger the outer pterygoid plate, and help may be obtained from the facts ascertained by the measurement of a number of skulls by my colleague, that in an adult male skull the average distance from the anterior border of the outer pterygoid plate—i.e., from the posterior lip of the pterygo-maxillary fissure—to the centre of the foramen ovale is about 18 mms., whilst in the female adult skull it is about 16·5 mms.; in both sexes the average measurements are a little greater on the right side, but in skulls that are abnormally large or small these vary to a corresponding degree. Should the above-mentioned pterygo spinous ridge of bone exist, it may be necessary to clip it carefully away in order to define the position of the foramen.

Fourth stage: Opening of the base of the skull.—Having thus exposed the foramen ovale and traced to it either the trunk of the undivided lingual and dental nerves, or the stump left from former operations, the base of the skull is now to be opened by means of the trephine. My intention in Cases 2, 3, and 4 was to remove a disc of bone having the foramen ovale for its centre, and for this purpose I employed a trephine with a handle set on a stem long enough to clear the cheek, and with a reversible centre-pin, one end of which was pointed as usual, the other blunt. The size of the trephine was such that it should remove a half-inch disc of bone; the crown was serrated obliquely on the outer side for a distance of a quarter of an inch in order that the trephine might clear itself of débris and not get jammed in the bone. The smooth-ended centre pin was projected from within the crown as far as possible, and introduced into the foramen ovale, so that the blunt point might protect the dura mater or other intra-cranial structures by pushing them before it. To do so the trephine was, roughly speaking, held in such a position that its axis was parallel to the external pterygoid plate. The handle of the trephine was then depressed and kept as far back as possible; but from the pressure of the soft parts it was always applied at an angle and not perpendicular to the surface, a proceeding not altogether undesirable, inasmuch as thereby the integrity of the carotid canal could be more readily maintained. The close contiguity of this structure had to be carefully kept in view during this stage of the operation; and, indeed, there is only the inner border of the great wing of the sphenoid, measuring from 2 to 4 mms. in thickness, intervening between it and the foramen ovale. By holding the trephine at this angle the outer segment of the bony circle was cut through first, and then the bone could be broken off on the inner side along the sutural line between the apex of the petrous bone and the great wing of the sphenoid, and thus the carotid canal remained uninjured. But even if it should be encroached upon, it by no means follows that the artery lying within will be damaged, as there is always a certain amount of space to allow of its expansion and other movements under the blood pressure. The portion of bone being now set free by an elevator, will fit like a collar over the stump of the divided nerve, and can be slipped over it. In one or two of my cases I noticed a definite constriction of the nerve at this point. In Case 4 I made an important modification by trephining in addition the great wing of the sphenoid anterior and a little external to the foramen. The trephine openings were then united by removing the bridge of bone between by a careful use of chisel and mallet. During this process the dura mater, which had been previously loosened around the openings, was protected by a spatula, and held up out of the way, for when unsupported the dura bulged through the opening. As will be seen by reference to the account of my cases which I append, this patient did well; but during the first forty-eight hours after the operation she had a certain amount of epistaxis, and also vomited some grumous material like coffee grounds, which was evidently altered blood. The source of this was a matter of considerable anxiety to me; it evidently did not come from either the sphenoidal sinus or the antrum, as these were in no way interfered with; but on careful examination of the base of the skull the relationship of the Eustachian tube, which had been previously overlooked by me, seemed clearly to indicate whence the bleeding was derived. This structure lies in immediate contiguity to the ridge of bone which forms the inner boundaries of the foramina ovale and spinosum. A groove will be found in this position in most skulls extending backwards to the point of attachment of the tube to the petrous portion of the temporal bone and forwards to the base of the pterygoid process; and this

FIG. 4.

Diagrammatic section of base of skull and lower jaw (after Andrewes), showing relation of trephine to foramen ovale and Gasserian ganglion.

region in the living subject is occupied by the cartilaginous portion of the tube. It is highly probable that in removing a disc of bone half an inch in diameter, with the foramen ovale as its centre, this tube will be encroached upon, laying the wound open to the risk of septic contamination from the pharynx. This consideration was one of several which induced me to alter my plan of operation in the last case I dealt with, and in consequence I applied the trephine to the great wing of the sphenoid a little anterior and external to the foramen, and in such a way that the circumference of the disc just impinged on its outer wall. (Figs. 3 and 4.) The opening thus made can be subsequently enlarged, if necessary, in any direction desirable. It must not be forgotten that the thickness of the skull is very unequal, being thinner on the outer margin of the trephine track than on the inner; and inasmuch as the instrument is necessarily applied at an angle, the outer half will be cut through before the inner. This fact renders damage to the dura mater possible, unless careful precautions be taken.



Fifth stage: Removal of the ganglion.—Having repressed the prominent dura with a spatula, the third division, which during all these preliminary proceedings has been carefully guarded, and round which a ligature should now

[4] Traité d'Anatomie Humaine, 1889, vol. I., p. 113.

Digitized by Google

be passed, is to be traced up to the ganglion, which should be loosened from its resting place upon the apex of the petrous portion of the temporal bone. No great difficulty need be experienced as regards the posterior half, but inasmuch as the anterior and upper portion is closely incorporated with the dural sheath, it is perhaps better to sever the connexion between the ganglion and the brain at its exit from the dura mater, and then to draw it forwards with a delicate pair of forceps. For this work a pair of fine hooks (Fig. 5) that have been made for me by Mr. Hawksley are most useful; one of them is an ordinary blunt-pointed hook, to pass round the nerves and free them from their connexions; the other has a sharp edge upon its concave aspect, to be used for cutting them through. It is quite possible that in dividing the root of the nerve just outside the dura a prolongation of the subdural space may be opened, and a small quantity of cerebro-spinal fluid escape through it; this, however, will be of slight extent, and is of no moment if the wound be kept aseptic. The second division of the nerve must now be dealt with, and this may be facilitated by enlarging the opening in the base of the skull in the direction of the pterygoid processes, and holding up the dural wall out of the way; it is to be divided just in front of the ganglion by the sharp hook. Having thus severed all its connexions except the ophthalmic division, the ganglionic tissue, which is exceedingly soft, may be pulled away piecemeal by forceps or by a small curette as recommended by Professor Andrewes. In this way the danger of wounding the cavernous sinus is reduced to a minimum.

FIG. 5.

Hooks for dealing with the ganglion (actual size). A, Enlarged sketch of hook, to show concave cutting edge.

Sixth stage: Reposition of displaced structures and closure of wound.—After the steps detailed above have been satisfactorily accomplished, the toilette of the wound must be attended to. The bleeding having been stanched, the parts should be thoroughly washed with a 1 in 40 solution of carbolic acid. The coronoid process may now be either sutured or removed; in my last case I removed it. Silver wire should be passed through the holes previously drilled in the zygoma, and it can thus be accurately adjusted. By this means the contour of the face will not be interfered with, the chances of necrosis or collapse of the zygoma prevented, and firm bony union assured. The integuments may now be brought together with a continuous fine catgut suture, care being taken to adapt the parts accurately to each other. No drainage-tube is needed, although I used it as a precautionary measure in my first two cases. If the wound has been occasionally irrigated during the operation, and all other antiseptic measures observed, primary union may certainly be expected, and it is most important from every point of view to obtain it. I am glad to say that no suppuration has occurred in any of my cases. To prevent accumulation of blood in the wound, gentle but continuous pressure by means of a purified sponge introduced between the second and third layers of the cyanide gauze will be found very efficacious. In addition to the face dressing, both eyes should be carefully covered with eye pads of salicylic wool, and lightly bandaged. A certain amount of shock necessarily follows such a protracted operation, and a subsequent elevation of temperature must be expected at the end of about forty-eight hours. Beyond this no symptoms of importance have been exhibited. The dressing has usually required changing once or twice in the first four days, at the expiration of which time it may be replaced by gauze fixed down with collodion. The stitches can be removed at the end of a week if they have not already been absorbed. The eye should be kept closed for at least four days, when the stitch in the lids may be removed; but it is safer to keep both eyes bandaged for a week, and the eye on the side operated on for three or four weeks.

I append a brief *résumé* of my cases:—

CASE 1.—Mrs. F. M——, aged sixty, sent to me by Dr. Padman of Bloomsbury, first came under my care in 1888. She had been suffering for five years from severe neuralgia, which had specially affected the inferior dental nerve of the right side. Counter-irritation and constitutional treatment having failed, the dental nerve was stretched at the entrance to its canal through the mouth on August 19th, 1888, and at the same time was divided at its exit from the mental foramen. This was followed by relief until March, 1889, when the pain returned with great severity, for which the lower jaw was trephined and half an inch of the nerve excised. Partial relief followed for a year; but in March, 1890, the lingual and dental nerves were cut down upon by deepening the sigmoid notch, and divided close to the base of the skull. The pain now recurred in the second division with greater intensity than before, any touch upon the jaw of that side producing a shock of agony terrible to witness. On April 2nd, 1890, I performed ablation of the superior maxilla, together with trephining around the foramen ovale, and removal of the ganglion. The patient made an excellent recovery with the exception of the ocular trouble already alluded to. The latest report, dated Jan. 28th, 1892, states that she is still quite free from pain, and her general health very good.

CASE 2.—Mrs. S C——, aged sixty-three. The neuralgia had commenced ten years before she came under observation in connexion with the teeth of the right lower jaw, and in spite of all treatment it spread to other branches and increased in severity. In 1884 all the teeth on the right side both of the upper and lower jaws were extracted, but without any relief. Drugs and local applications had no effect. When first seen by Dr. Ferrier and myself the case was typical, a paroxysm being elicited by almost any movement of the jaw or stimulus from without; the pain chiefly affected the lingual and dental nerves and the back of the orbit, and shot down into the palate. In consequence of the evident implication of the second as well as the third division of the trigeminal, Dr. Ferrier recommended that the Gasserian ganglion should be dealt with at once, without having recourse to any minor measures. This was done on Jan. 29th, 1891. The foramen ovale having been exposed through the pterygoid region was trephined, and the opening extended with a larger trephine. The ganglion was then removed piecemeal. The patient made an uninterrupted recovery. The eye was anæsthetic when exposed four days after the operation, and the conjunctival reflex was diminished for some time, but no trophic disturbance manifested itself. Slight difficulty in mastication was subsequently experienced, but this soon passed off. There has been no recurrence of the neuralgic pain, and the patient was seen by me only a few days ago.

CASE 3.—Mrs. E. K——, aged sixty-three. The neuralgia in this patient dated back for about five years, starting in the inferior dental nerve as the result of carious teeth, which were removed, but without benefit. About February, 1890, I divided the inferior dental and gustatory nerves close to the foramen ovale by deepening the sigmoid notch. This was followed by relief for about a year, when she was readmitted to hospital with pain in the second and third divisions, but especially referable to the superior maxillary. The operation was performed on Oct. 29th, 1891, by the usual incision and with the usual precautions. The great wing of the sphenoid and external pterygoid plate having been cleared, what was at first considered to be the foramen ovale was exposed and the trephine applied; the appearance of some orbital fat, however, through the trephine hole indicated that the pterygo-maxillary fissure had been mistaken for it. The raspatory was again employed further back, and the foramen ovale clearly demonstrated. Owing to the previous operation there was less hæmorrhage than usual, but the tissues were much matted together, and so interfered with the application of the trephine. The base of the skull was opened and as much of the ganglion as could be seen removed. The wound was treated as usual, both coronoid and zygoma being wired, and healed without trouble. For a time the right eye was painful and the conjunctiva congested with some œdema of the lids, but there was no disturbance of the corneal epithelium. The greater portion of the right side of the face was

Digitized by Google

anæsthetic for the first five days after the operation, but this gradually diminished in extent; so that when she left the hospital on Nov. 30th there was a partial return of sensation over the first and third divisions. The cheek, lower eyelid, and upper lip had, however, completely lost their sensibility to touch and pain, and the right side of the tongue was still dull. The patient returned a few days ago complaining of inability to open the mouth, which I remedied by forcible depression of the lower jaw under an anæsthetic. The only other complaint was a slight occasional pain and intolerance of light in the right eye.

CASE 4.—Mrs. D——, aged thirty-seven. In this patient the disease seems to have originated about twelve years ago in a bad tooth in the right side of the lower jaw. In 1887 I trephined the lower jaw and removed half an inch of the inferior dental nerve, with temporary relief, but the pain recurred under the right eye, in the tongue, and again along the jaw. In July, 1890, portions of the inferior dental and gustatory nerves were removed by deepening the sigmoid notch, but the relief given by this proceeding was of short duration, and the pain recurred with more than its old severity, extending down into the neck and up to the temple. On Nov. 5th, 1891, I operated for the removal of the Gasserian ganglion. The operation was performed in the way detailed above and the skull trephined in two places, one posteriorly having the foramen ovale for its centre, and the other a little anterior and external to it, the intervening bridge of bone being removed by chisel and mallet. In consequence of the thickened state of the third division, it was difficult to draw the disc of bone over the stump, but when this had been accomplished the foramen was found to be very small. By detaching the dura mater the ganglion was seen and even felt by the finger, and by cutting through the different divisions was removed; the opening in the dura for the passage of the root of the nerve was clearly defined, and through this a small quantity of cerebro-spinal fluid trickled. During the removal of the ganglion the dura, which had a tendency to bulge, was lifted by a bent spatula. The after history of this case has been satisfactory. I have alluded already to the fact that some epistaxis and vomiting of altered blood occurred, probably from damage to the Eustachian tube. The wound healed throughout by first intention. One week after the operation the sensation of the right side of the face and tongue was carefully tested, and found to be much decreased, although not totally absent. Between two and three weeks after the operation the right eye became somewhat congested and irritable from the development of a crop of small subepithelial vesicles on the lower fifth of the cornea, which burst in a few days and left a superficial ulcer, which, however, readily healed under suitable treatment, and the congestion gradually disappeared. The eye pad was in this case retained for six weeks. The patient was examined on Jan. 27th, 1892, and there has been no recurrence of the pain.

CASE 5.—Mrs. B——, aged thirty-seven, sent up from Derby Infirmary by Dr. Taylor, had suffered from epileptiform tic of the second and third divisions for seven years. She had teeth extracted from upper and lower jaws on the affected side, but this rather increased the trouble than otherwise, and the usual medical treatment had been tried without benefit. Paroxysms were excited by masticatory movements, even after removal of the teeth; they lasted about two minutes, and recurred about every half hour. They could also be elicited by pressure over the points of exit of the second and third divisions. After consultation with Dr. Ferrier, and in consequence of the evident implication of both the supra- and infra-maxillary divisions, it was decided to cut down upon the Gasserian ganglion.—Jan. 16th, 1892: The usual incision was made, and the zygoma, which in this case was very slender, was exposed, drilled, sawn through and turned down. The anterior saw cut was made close to the malar bone, which was drilled on the slant to clear the root. The coronoid process was cut through, and the temporal muscle turned up and held out of the way. Troublesome bleeding from the pterygoid plexus of veins ensued, interfering for some time with the identification of the trunk of the internal maxillary artery, which was, however, finally secured. The external pterygoid muscle was scraped away from the skull, exposing the great wing of the sphenoid, together with the anterior margin of the foramen ovale. The trunk of the nerve emerging from this was now isolated, ligatured, and divided. The trephine was applied to the great wing of the sphenoid anterior and external to the foramen ovale, the circumference of the trephine track just touching it. Owing to the thinness of the bone in this position the edge of the trephine wounded the dura mater, so that the temporo-sphenoidal lobe could be subsequently seen. The trunk of the third division was lifted from the foramen into the trephine hole and traced up to the ganglion, which was then loosened from its connexions, and probably the posterior half only removed. Before closing the wound the coronoid process and about an inch of the temporal tendon were excised. The patient was somewhat collapsed after the operation, and complained of pains in the top of the head and in the limbs. The temperature rose to 101·4° on the second day, but has since been normal. There has been none of the old pain since the operation. I shall anxiously watch the future progress of this case, for I think it highly probable that the anterior half of the ganglion was left completely undisturbed, and the cerebral root but partially divided, an occurrence attributable to the limited opening I made in the skull and to the troublesome hæmorrhage protracting the operation. The anæsthetic area in this case is not so complete as in the others, and seems mainly confined to the third division. The sense of taste is completely lost on the right side of the tongue; this was carefully tested by Dr. Ferrier a few days ago with salt, sugar, and quinine.

A sixth case was operated upon in Chicago on Nov. 7th, 1891, by Professor Andrewes in a similar manner. The patient was a woman aged fifty, who had suffered for five years from "frightful pain along the inferior maxillary division without being able to obtain any relief, the act of swallowing being especially associated with the paroxysms." He trephined the base of the skull by the side of the foramen ovale and broke up the ganglion thoroughly with a curette. The patient, who was very weak, felt the shock considerably, but rallied after a few hours, and was free from neuralgic pains. There was complete benumbing of all the parts supplied by the ganglion, and swallowing was no longer painful. The motor oculi nerve was paralysed, showing that it had been injured, probably by the curette. In ten days she was able to return to her home fifty miles distant, although the wound was not quite healed, and it suppurated slightly afterwards. I had another communication from Professor Andrewes recently, dated Jan. 15th, 1892, stating that this patient had remained free from pain; that the paralysis of the motor oculi proved only temporary, but there was a slight tendency to pericorneal ulceration of the right eye. He also sends me particulars of another case in a woman sixty-two years of age, the disease being on the right side, and involving the second and third divisions. He had previously removed the inferior dental branch close to the foramen ovale. The operation was performed in the middle of last December in the same way, by trephining just external to the foramen ovale, and removing the ganglion with a sharp curette. There was troublesome hæmorrhage during the operation. Up to the time of his writing the patient was perfectly free from pain.

Results of operation.—In considering the results of partial or complete removal of the Gasserian ganglion, the first question which has to be answered is naturally "What effect has this proceeding upon the pain?" Up to the present time we are able to give a satisfactory reply; all the five patients whom I have treated in this way have remained free from the typical and terrible paroxysmal attacks from which they had previously suffered. It is true that my first case was done only twenty-two months ago, and the last only sixteen days; consequently, it is too early to speak with confidence as to the permanent character of the relief; but the results hitherto obtained are sufficiently encouraging to lead me to continue in the same line of action. Absolute immunity from any kind of pain can hardly be expected after such a considerable disturbance of the structures at the base of the skull, and for some time there may persist a sore and stiff sensation about the region operated on as well as pains in the head; but these are not considered of any moment by patients who have previously suffered such intense agony. The interference with the movements of the lower jaw is undoubtedly inconvenient, and renders the process of mastication a little difficult; but I hope that this may be avoided in the future by the removal of the coronoid process. As to the effect upon the distribution of the sensory fibres of the fifth nerve, it is interesting both from the clinical and physiological aspects to observe the rapid diminution of the anæsthetic area, and it would appear that the

Digitized by Google

distribution of sensation is taken up by the neighbouring branches much in the same way as arterial anastomosis takes place in the vascular system. This re establishment of sensation is a fact which cannot be disregarded prognostically, although it is not necessarily the precursor of a relapse. The appearance of the side of the face operated on is characteristic of trophic disturbance: the skin has a shiny, somewhat injected look, whilst the hollows in the temporal, pterygoid, and maxillary regions on that side clearly demonstrate the existence of muscular atrophy and cicatricial deposit. The effect upon the nutrition of the eyeball is decidedly serious. In the first case, as is well known, the organ was lost, a result of suppurative panophthalmitis, and in two of the other cases the nutritive state was for the time considerably depressed. It is probable that the trophic centres for its nutrition are contained in the upper and anterior segment of the ganglion, and if this be so, the chances of damaging the eye may be lessened by leaving this portion intact, even though the trunk of the nerve be divided behind the ganglion. On the other hand, the interference with one part of the ganglion may induce degenerative changes in the remainder, which will effectually prevent a recurrence of the malady, and yet will not be sufficient to cause permanent damage to the eye.

Such are the results, Mr. President and gentlemen, both of my own observations and experience, together with that of others, in this department of surgery, and from them I venture to draw two very definite conclusions: (1) That in severe cases of epileptiform neuralgia both medical and surgical treatment have hitherto been unavailing to give permanent relief; and (2) that exposure and partial extirpation of the Gasserian ganglion through the base of the skull, though admittedly difficult, need not endanger life, and at present holds out the best prospect of dealing with these intractable forms of trigeminal tic. The test of time and further experience can alone decide what value will be finally attached to this measure; but at any rate the outlook is hopeful, and let us trust the future will not belie our present expectations.

(During the lecture, which was illustrated by diagrams and microscopical specimens, Mr. Rose demonstrated the different stages of the operation on the cadaver.)

THE BEARING OF RECENT BIOLOGICAL RESEARCHES ON THE PRACTICE OF MEDICINE AND SURGERY.

BY G. SIMS WOODHEAD, M.D., F.R.C.P.EDIN.,
DIRECTOR OF THE LABORATORIES OF THE ROYAL COLLEGES OF PHYSICIANS (LOND.) AND SURGEONS (ENG.).

(*Concluded from page 245.*)

THIS question of internal metabolism has a far more important bearing on treatment in disease than would at first sight appear. It is a well-recognised fact that all cells, when stimulated in excess of their powers of taking up nutriment, utilise for food material the protoplasm of which they themselves are made up: and altered metabolic processes, ending in grave degenerative changes, go on. We find that a cutting off of the food supply has a similar effect. Taking, as an example, the muscle fibre of the heart or the protoplasm of the liver cells, we find that in the course of an attack of fever, under the stimulation of a high temperature—under the influence of which metabolic activity is always increased, and under the action of the toxic substances, associated with the production of the disease, circulating in the blood—the protoplasm passes through a stage of cloudy swelling, which is evidence of the increased activity of the protoplasm, and then, if the process is continued, merges into well-marked fatty degeneration. In certain very acute diseases such degeneration is not confined to the excretory glands or to the heart muscle, but has frequently been observed in both nerves and muscles, especially in connexion with diphtheria and typhoid fever. From what we know of the clinical symptoms presented in influenza there can be little doubt that here similar marked metabolic changes may be initiated during the course of an acute toxic condition, the result of the vital activity of the specific organism associated with this disease.

Wherever this condition occurs two things should be carefully borne in mind: (1) that recovery may take place if the fatty degeneration is not so far advanced that the active protoplasm of the cells is absorbed; (2) that for recovery to take place it is essential that the cells should be placed under the most favourable conditions as regards nutrition; that not only should they not be over stimulated, but that they should have absolute rest, as far as possible, from their ordinary work. How often are these conditions kept in view when patients are recovering from acute specific fevers? Some physicians, undoubtedly, arguing very rightly from the condition of the pulse in these diseases that the patient is in a greatly enfeebled condition, order rest for lengthened periods, forbid exertion of any kind, especially such exertion as is calculated to throw even a moderate strain on the heart. They know how frequently dilatation follows any exertion taken before the tone of the heart muscle has recovered; but how many bear the same points in mind as regards the liver, the kidney, the voluntary muscles, and even the brain cells and nerve fibres during convalescence from similar diseases? How often, except in such conditions as scarlet fever, do we consider the enfeebled condition of the kidneys, and take into our calculations the diminished powers of the liver to perform its ordinary functions; whilst, passing still further back, what consideration do we give to the lymphatic glands and the tissues of which they are composed, tissues which during the acute stages of the specific diseases have had so much extra work thrown on them, and which must require rest and careful nutrition in order that they may be brought back to their original healthy condition? Whoever considers that it is necessary to think of the leucocyte and its near relation the connective-tissue cell in this connexion? It is only when we come to look on them as extremely active agents in nutrition, metabolism, and excretion that we bring ourselves to appreciate their importance, and to recognise the necessity of getting to know something of their life history and of their relation to disease.

The leucocyte has been looked upon by different observers as a separator and carrier of fat, of glycogen, and of certain excretory products; as a producer of peptone, as a scavenger and as a policeman; as a prominent factor in the process of keeping the fluid constituents of the body in a state of equilibrium; as an important element in the causation of coagulation; in fact, according to the special line of work on which men have been engaged, so have they assigned functions to the leucocyte. The bulk of evidence that they have been able to bring forth in support of their theses, moreover, compels us to accept it as possible that they are all correct in so far as the leucocyte seems to play no secondary part, at all events, in many of the above-mentioned processes. We are, in fact, brought back to the biological standpoint that, for the explanations of many of the most important questions in general physiology, we must refer to the processes that are going on in the elementary cells of the body, where we may find bound up in one comparatively slightly differentiated mass of protoplasm all the functions that are more highly developed, each in its own form of cell.

Many writers, especially those who speak of themselves as being intensely practical, are in the habit of sneering at laboratory work and of speaking lightly of the acquisition of new methods and of the discovery of isolated facts in various regions of biological research. But when we come to go over the history of medicine and to compare our knowledge gained empirically with that gained by experiment, we cannot but be struck with the difference in character of the knowledge gained by the two methods: in the one case the fact remains, however it may from time to time be interpreted; whilst in the other case everything connected with it is constantly changing. Of the second method little need here be said; but of the first method we may take for our example the condition of the blood and its relation to certain diseases, and of its importance in certain modes of surgical treatment. In the study of coagulation, facts have been gradually accumulated which, taken together, have from time to time enabled physiologists to throw light on the processes that take place during the coagulation of the blood. We have had described, for instance, the effect of the presence of fibrin ferment and tissue fibrinogen in the blood, and the influence which the presence of soluble lime-salts exerts. Each of these facts in itself had a comparatively transitory interest for the practitioner, because not one of them promised any benefit to his patient.

Digitized by Google

Dr. A. E. Wright,[1] however, following up the researches of Schmidt, Wooldridge, Hammarsten, Ringer, Green, Arthus, and Pagès, each of whom has contributed some isolated fact to our knowledge, has been able to apply in a most interesting fashion the knowledge so obtained, and to render this work useful from the point of view of treatment. He employs a fibrin ferment solution, to which is added 1 per cent. of calcium chloride, as a styptic, which brings about coagulation of the blood. It has the very great advantage that, whilst clotting the blood itself, it has no deleterious action on other tissues, as he says "such a styptic exerts an elective influence on the blood, and is perfectly inert when brought in contact with other tissues, and is therefore perfectly painless in its action. Further, the coagulative influence which it exerts upon the blood probably takes place along the natural lines upon which normal blood coagulation occurs." It undoubtedly brings about extra-vascular coagulation. At first sight it might appear to be an equally easy matter to induce coagulation within the vessels, and to utilise the method in practical medicine; but in such cases dangerously large quantities had to be employed. It was even thought that by injection of tissue fibrinogen into the vessels coagulation might be induced, and that a means of checking internal hæmorrhage had thus been obtained. Experiment, however, proved that in some cases the coagulability was certainly increased, and, where smaller quantities were employed, the coagulability was considerably diminished both before and after the blood was shed; and it was found that in these cases the injected materials were transformed in the circulation into substances (probably albumoses) which rendered the blood less coagulable than in the normal condition. When, however, a solution of calcium chloride—a substance which, as we have already seen, is essential for the coagulation of the blood—is injected clotting takes place wherever the vessels are injured, but apparently at no other points. It is quite unaltered by contact with the blood itself, and thus is ready to help on the process when the other conditions necessary for coagulation are present. The importance of this in cases of hæmophilia, of post-partum hæmorrhage, and of internal hæmorrhage of various kinds, in aneurysms where the walls are somewhat altered, and where the conditions for clotting are certainly favourable, can scarcely be over-estimated, and the internal administration of calcium chloride as a styptic may prove to be of enormous advantage. This has been worked out from the experimental point of view, and the fibrin ferment and the calcium chloride styptic have proved so useful in stopping hæmorrhage when applied externally that we may confidently anticipate this styptic will come into very general use in the treatment of refractory hæmorrhages of various kinds.

Many other experiments on the blood have led to the acquisition of knowledge the importance of which we are not yet in a position accurately to estimate. A new kind of corpuscle has been discovered, an increase in the number of leucocytes in the blood has been demonstrated after the injection of tissue fibrinogen and of other proteid substances, and conditions very similar to those met with in leucocythæmia have been produced by the injection of certain of the proteid products met with in the course of various diseases, and many theories as to the relation of this increased number of leucocytes in the circulation to the protection of the individual against disease, especially those of a specific character, have been formulated. The relation between the increased number of leucocytes to an increase of peptone[2] and of uric acid[3] in the urine has been traced in cases of leucocythæmia, and has similarly been followed out in the course of leucocythæmias produced experimentally, and we may anticipate that before long other information may be obtained by a further study of these facts.

In no region of experimental research has there been a more immediate outcome as regards treatment—especially from the surgical point of view—than in that of nervous pathology and physiology, and the whole band of enthusiastic students of a most interesting branch of physiology may congratulate themselves that they, at any rate, have not carried on their work in vain. The localisation of function in certain areas of the brain—though still a matter for discussion and experimentation—has opened up a new region of surgery, a region in which our best surgeons have excelled themselves, and one that has afforded brilliant opportunities of obtaining most successful results to some of our younger surgeons, trained in the most exact methods and prepared by a long course of accurate experimentation, in which the importance of carrying out exact details and new methods had been insisted upon in an almost exaggerated degree. The result is that in no domain of surgery has such satisfactory results, as far as the welfare of the patients is concerned, been obtained. We cannot maintain yet that the localisation of the paths of sensation and of motor impulse in the cord and in the brain have been definitely worked out, but we can see before us a prospect which is gradually opening up; each fresh point gained opens up a wider view, and one that promises some important practical results, for no scientific worker, however fully he may be imbued with a love of truth for its own sake, can be content with the outcome of laboratory work were he not assured that the ultimate practical benefits to the science and practice of medicine, the alleviation of suffering, and the prevention of disease would accrue from the knowledge that he may be able to acquire.

The triumphs of cerebral surgery by contrast throw into comparative insignificance the work that has been done on the spinal cord; but for all that great strides are being made in the advancement of our knowledge of the physiology of the cord, and we may rest assured that ere long this knowledge will receive further practical application, as glimmerings of light as to the paths of conduction are already being obtained. Moreover, the nature of many of the pathological processes in the cord is now much more fully understood than it has been at any previous period in the history of medicine; the results of concussion, the protean nature of which for so long puzzled railway surgeons and others, have received their explanation on the assumption, now proved to be correct, that they are due to inflammatory changes set up, running their course comparatively slowly, but leading, nevertheless, to interference with the functions and with the conduction of sensory or motor impulses along the nerve tracts. Such conditions as locomotor ataxia and peripheral paralysis are now explained as being the result of neuritis and myelitis. It has of course long been argued that some of these forms of disease are the result of such a condition as syphilis, even before the changes met with in syphilis were supposed to be due to the action of a specific micro-organism and its products; and now that the degenerative changes in nerves, met with in such diseases as diphtheria and typhoid fever, have been associated with the presence of an organism and its poison, we can see what a fertile field of research is opened up, and what ultimate practical results may be obtained from a study of earlier experiments and observations. Any one of the series of observations above mentioned could alone give us little help in our study of these disease processes; but when they are collated and arranged, and deductions are made as a result of their study, we are led from point to point, and ultimately we may hope to gain that accurate knowledge which will enable us to claim for this branch of medicine and surgery that it is not merely an empirical handicraft, but both an art and a science in the truest sense of the word.

One fact that has been brought home to us very forcibly during the last few years is that we have been arguing too directly from the general to the special, when our knowledge of the general has been far too limited; we have been discussing the modifications and special transformation of protoplasm before we have thoroughly understood what protoplasm is; we have assigned special functions to special kinds of cells, and have assumed that on the development of these special activities most of the other functions have been obliterated. We are now gradually beginning to find out that we have been apt to confine our studies too closely to the extremes of undifferentiated protoplasm and of cells in a high stage of differentiation, and that we have ignored all those intermediate stages by the study of which alone we are able to gain a wider and more accurate knowledge of cell activity and cell transformation. Moreover, we are now coming to see that animal and vegetable protoplasm are not so divergent as regards their character as many would have us believe, and that now, with the modern methods of bacteriological research at our disposal, we may study many of the central truths of physiology in the minute specks of vegetable protoplasm known as bacteria.

In them we may find combined not only the characters common to all protoplasm, but we may also observe in them some of the highest forms of specialisation of function and energy production. In them we have organisms existing under such conditions and proliferating at such an enormous rate that we are able to modify the surroundings through an enormous series of generations, and to watch the modifications brought about under different modified conditions.

Now that bacteria have been accepted as being the cause of specific infective diseases, we are able to explain certain of the peculiarities of the outbreaks of epidemic diseases, and, having traced these to their source, our prospects of being able to modify or to cut them short are certainly much brighter than they have ever yet been. Even the mystery-enshrouded influenza must gradually yield some of its secrets, and it is already reported that isolation and disinfection have done much in certain crowded institutions, such as asylums, to cut short the ravages of the epidemic. If we are to accept what those who have studied the organism found in the tissues and cavities of the body in this disease have told us, we have an organism which, though under certain conditions extremely virulent and readily transmitted directly from patient to patient, soon loses this virulence when grown outside the body; it should, therefore, with proper precautions, be quickly banished from our midst. If people will once accept these facts, the spread of the disease might be rapidly checked. One important point to be borne in mind is that this modification of virulence does occur, and for some reasons it is most unfortunate that this should be the case, as in this modified form the attacks of the disease are so mild that they are treated with contempt by those who suffer. On the other hand, it should be remembered that in any disease, if the organisms associated with it are not killed off, their virulence in most instances becomes increased; this appears to be specially the case in influenza. It is this same organism, rendered virulent by its passage through a series of patients, acting on weakened tissues that proves so fatal; but the relation between the milder attacks and the severer forms of the disease has till quite lately been entirely ignored, with the consequence that few precautions as regards isolation and disinfection have been taken, and the disease has been allowed to spread, with the result that the organism from the mild case, finding its way to people of lowered vitality and with little tissue resistance, has set up a severe and often fatal form of the disease.

This tissue resistance is so intimately bound up with the life history of the cell, with its powers of nutrition, and the facilities for excretion of effete matter, with its power of taking up foreign bodies of all kinds, pigment, bacteria, &c., and with its capacity for converting these into inert matter, and afterwards utilising them for its own purposes, or of getting rid of them altogether. It has received special attention since the study of bacteria was recognised, and so much additional knowledge has already been obtained, that we may confidently look forward to a time when we shall be able to predicate what will be the effect of the introduction of tubercle bacilli, of leprosy bacilli, or of other pathogenic organisms, into different parts of the body, where they may be attacked by the different kinds of cells; we shall be able to point out what kinds of organisms are able to bring about degeneration of the various kinds of cells, and whether they do it directly through the action of their protoplasm, through the secretion of poisonous products, or through the presence of their dead protoplasm or of substances contained in it; we shall also be able to state which organisms hunt in couples as it were—the one by its products preparing the way for the advance of the other,—so that where we find it difficult to get rid of both organisms we may be able to deprive one of its power of doing harm by destroying, banishing, or rendering harmless the other; but, more important still, we shall be able to determine the conditions under which the various cells, tissues, and fluids of the body are best enabled to resist the advance and action of these organisms.

Although we are already well versed in the general laws of health, and, theoretically, are ready to meet every kind of disease by which we may be attacked, we have still not arrived at the conviction that, economically, the greater attention paid to the carrying out of mere preventive measures, such as better nutrition for the children of the poor, better conditions of hygiene, greater opportunities for exercise in the fresh air, would be a great saving to the State; whilst any expense that such improved measures might entail would be more than recouped by the great gain to the community as a whole, not merely through the better health and diminished death-rate in our present poverty stricken and overcrowded quarters, but also by the diminution in the number of centres from which disease may spread to those quarters where the conditions of life are much more favourable.

ACUTE CATARRH OF THE LARYNX.

BY GORDON HOLMES, M.D.,

PHYSICIAN TO THE MUNICIPAL THROAT AND EAR INFIRMARY, LONDON; CONSULTING PHYSICIAN TO THE SHEFFIELD EAR AND THROAT HOSPITAL.

HISTORY.

ON account of the extremely obvious character of the symptoms of this disease, especially the hoarseness, it would naturally be recognised at an early period in the records of medical science. Through the default, however, of anatomical knowledge, we should not expect it to be differentiated with any degree of accuracy from other throat affections which produce a modification of voice. Before the time of Hippocrates all maladies of the throat were grouped together under the common name of *kynanche*[1] (a strangling or stifling), but later on this term was restricted to internal cases. In the writings of the Asclepiadæ a distinction is first made between those instances in which the internal parts of the throat are visibly affected and those in which the disease is so low down as to be out of sight. In the treatises ascribed to Hippocrates a number of descriptions are given[2] suggesting at one time or another every known form of laryngitis, but none is presented with much pathological discrimination. About 70 A.D. Aretæus[3] apparently coins the word *synanche* to designate acute affections of the larynx, the organ by this date having become known with some anatomical and physiological accuracy. About the same period Cœlius Aurelianus and Galen, especially the latter, treat of laryngeal disease with some precision, and Galen[4] even attempts a description of those maladies which involve the "internal tunic or pellicle" of the larynx. With them we may leave the ancients, and pass through the Middle Ages to the beginning of modern times. Taking Fallopius[5] as a representative of the epoch, we do not find that catarrhal laryngitis is as yet clinically separated from the more serious forms. Only in the middle of the seventeenth century do we meet in Boerhaave[6] brief and definite allusions to the catarrhal varieties. After his time laryngeal disease became more attentively studied, chiefly owing to the researches of Morgagni,[7] who, having met with a striking case in the post-mortem room, afterwards attached great importance to lesions of the larynx. About 1829, in the treatise of Albers,[8] we first have some accurate description of acute catarrhal laryngitis; and nearly at the same time Guersant[9] began to call attention to the malady, as manifested in children, under the name of "pseudo-croup." Finally, with the introduction of the laryngoscope, in the writings of Ruehle,[10] Türck,[11] Gerhardt,[12] and Mackenzie,[13] the general features of the disease were made familiar to the profession.

SEMEIOLOGY.

1. *Subjective.*—At the outset a slight sensation of swelling or obstruction is felt in the larynx, which may be accompanied by more or less perception of abnormal heat in the part. Hence the patient tries to clear his throat by coughing, but with the apparent result of aggravating the disorder. Pricking or stinging sensations are soon developed in the interior of the vocal apparatus, causing the face to become flushed,

Digitized by Google

and distressing efforts are made to get rid of the inconvenience by coughing. Soon a roughness or soreness, chiefly perceptible in the vicinity of the glottis, results, and the sufferer now begins to refrain from coughing, because it hurts. At the same time a slight stiffness of the throat is felt at each act of deglutition, amounting sometimes to actual pain, which, however, in uncomplicated cases never extends beyond a minor degree. Whilst the disease progresses, hoarseness becomes marked and permanent, and more or less effort is required in order to produce the laryngeal tones. Such, in adults, is the ordinary picture of the establishment of this malady, which most frequently advances thus far within about thirty-six hours. After the first day or two the cough is likely to become spasmodic or involuntary, and accompanied by a limited amount of expectoration. At the same time the slight febrile symptoms, which are present at the outset of the disease, pass away. In a period varying from five to fifteen days, according to the intensity of the attack, the laryngeal symptoms disappear, and the patient regains his usual health. Some weakness or modification of voice, especially in those who make a professional use of the vocal organs, may, however, persist for some weeks, or even months. In children the phenomena of acute catarrh of the larynx are usually invested with certain peculiarities, on account of which it has merited the names of "laryngitis stridulosa" and "false croup." During the daytime the symptoms are usually much less prominent than in the adult. In fact, the existence of the malady is, as a rule, only revealed in the middle of the night, when the patient wakes up in a condition which seems to threaten imminent suffocation. The child suddenly starts up in bed, his breathing is hurried, and accompanied with a sharp, crowing sound at each inspiration; there are frequent accessions of a ringing, convulsive cough. His voice is markedly hoarse, and he speaks with difficulty owing to the urgency of the dyspnœa. This crisis lasts for from twenty minutes to two or even three hours, when the child, becoming somewhat exhausted, again composes himself to sleep. In the milder cases on awakening in the morning he shows scarcely a sign of the severe attack passed through during the night. Generally, however, more or less hoarseness and "croupy" cough continue during the day, whilst the nocturnal phenomenon may return for several nights in succession, though almost invariably with a diminishing urgency.

2. *Objective.*—(*a*) If we examine a case of acute catarrh of the larynx laryngoscopically, we shall usually find very marked evidence of hyperæmia. The vestibule of the larynx is often completely suffused with a vivid redness, whilst considerable swelling is commonly perceived in those parts which contain much loose connective tissue—i.e., the ary-epiglottic folds, the ventricular folds, and the intra-arytenoid fold. At the same time small patches or striæ of a greenish mucus may be observed adhering to the congested surface in various positions. As to the vocal bands, their appearance varies considerably in different instances of this malady. Often they present merely a soiled hue, showing, perhaps, one or two pink spots on their upper surface. In other instances they are decidedly congested, exhibiting a slight but diffuse pink tinge over their whole extent. Sometimes, again, they are so red as scarcely to be distinguished in colour from the adjacent mucous membrane. A proportion of cases are even met with in which an exaggerated hyperæmia of the vocal bands is practically the only objective sign of the malady. In most examples the morbid condition can be observed laryngoscopically to extend for a variable distance down the trachea. When it is strictly limited to the larynx it is generally believed, and probably with truth, that cough is then conspicuous by its absence, but of course voluntary efforts to clear the breath-way are present in all instances. (*b*) As regards expectoration, at first very small quantities of a clear, viscid mucus are brought up, but after two or three days the discharge becomes somewhat more abundant, thinner, and of a greenish hue—in fact, mucopus. Not unfrequently it is streaked with blood, visible macroscopically, and almost invariably blood-corpuscles can be demonstrated with the microscope. Concomitantly pellets of inspissated mucus are expectorated. They are of a greyish or even blackish colour, indicating doubtless that they have remained for some time in the current of inspiration and become soiled by dust or sooty particles drawn in with the external air. If the patient is obliged to breathe habitually with the mouth open, this soiling of expectorated matter by atmospheric impurities is always much more manifest. (*c*) As the hoarseness becomes established the gravity of the vocal tones is generally much increased, but the voice has a great tendency to break suddenly into a higher falsetto note, especially at the beginning or end of a sentence. In females usually, and in males rarely, actual aphonia results, resonant phonation is abolished, and the voice is reduced to a whisper. (*d*) Some local tenderness is present as a rule, so that pressure with the fingers on and about the larynx hurts to a limited extent. (*e*) Respiration is in adults never interfered with to any objective extent. The nocturnal dyspnœa of children suffering from this affection has already been sufficiently described.

Pathogenesis.—Under this heading we have to deal with *predisposing* and *exciting* causes. Among the former the most prominent place must be accorded to youth, for the malady is comparatively rare after middle life. Thus, out of 173 cases of which I have a record, I find 117 were under twenty-five years of age. The male sex also predisposes markedly, only forty-two of these instances being females. The malady is naturally more common in delicate persons, especially those affected with some decided dyscrasia—such as scrofula, tuberculosis, or syphilis. Young persons of this class often have an attack regularly recurring during some part of each winter. Mode of life also favours the occurrence of the disease, and those who are exposed to vicissitudes of weather—such as field labourers, cab-drivers, costermongers, &c.—are more likely to be attacked. As a secondary affection it is frequently met with, and is thus not uncommonly seen associated with scarlet fever, measles, small-pox, typhoid fever, gout, and rheumatism. As to exciting causes, in the first rank stands taking cold by any of the ordinary accidents which lead to exposure. Amongst medical practitioners of the older school a belief very generally prevailed that the kind of cold arising from getting the feet wet, did, as a rule, expend itself in the production of a laryngitis. I have not, from personal experience, been impressed by the efficiency of this etiological factor, but some considerable weight must be allowed to any practical inference which has attained to the rank of a creed amongst a large number of skilled observers. Cases originating in cold are usually met with in damp, chilly weather, such as is most frequent in this climate during spring and autumn. Frosty conditions of weather are less conducive to the disease. Next in order among exciting causes we have those peculiar states of atmosphere which are specifically irritative to the air passages, and are commonly evidenced by the epidemic occurrence of influenza, hay fever, certain forms of coryza, and bronchitis. With such affections a catarrh of the larynx, more or less pronounced, is generally associated. Third on the list we may place instances arising from straining the vocal apparatus, as in loud shouting, screaming from fright, and even inordinate vocal efforts of a professional kind, which, however, are ordinarily linked to laryngeal manifestations of a chronic nature. In this division fall those examples sometimes encountered in females as the sequence of hysterical attacks accompanied by persistent piercing cries. Lastly may be placed those rather rare cases arising from direct irritation of the laryngeal mucous membrane—viz, from inhalation of some irritating gas (chlorine, nitrous acid, steam, chloroform, ether, &c.) or from the contact of a foreign body accidentally finding its way into the larynx, even from the incautious and too frequently repeated introduction of laryngeal instruments for the extraction or treatment of growths &c. In one instance which came under my notice a piece of silver nitrate, becoming detached from the holder, lodged in the hyoid fossa, and in twenty-four hours produced a very violent inflammation of the corresponding side of the larynx; the patient, an old woman, succumbed. With respect to the frequency of the malady compared with that of other diseases of the larynx, no reliable statistics are forthcoming. Here, as in every other department, the annals of special hospital practice show an enormous preponderance of chronic disease. But all such statistics are vitiated by the fact that acute cases comparatively seldom reach the hands of the special practitioner, either in private or at an institution. The specialist, indeed, is nearly always engaged with cases which have previously undergone treatment at other hands. I may say that out of about 6000 instances of laryngeal disease I can collect less than 200 of acute catarrhal laryngitis. Nevertheless I should judge it to be at least three times as frequent as these figures indicate.

(To be concluded.)

TWO CASES OF RUPTURED BLADDER.

BY P. A. LLOYD, F.R.C.S.ENG.,
SURGEON TO THE PEMBROKESHIRE AND HAVERFORDWEST INFIRMARY.

CASE 1. *Extra-peritoneal rupture of the bladder; supra-pubic drainage; recovery.*—Miss H. R——, aged twenty-one, was in a railway accident on March 4th, 1890; she had left London at 8.50 P.M. on the 3rd, and the accident occurred at 3.30 A.M. on the following morning. The carriage in which Miss R—— travelled was telescoped, and she says she remembers some heavy weight—she thinks the carriage seat—lying on her abdomen. When first seen shortly after the accident she could not stand or walk on account of pains in the groins and thighs; no fracture or injury to the femora or pelvis could be detected, and there were no bruises or abrasions of the skin. No urine had been passed since leaving London. The patient was suffering from shock and vomited repeatedly. The temperature was subnormal and the pulse small and frequent.—March 5th: No urine having been passed, a catheter was used this morning, and about an ounce of bloody urine drawn off. A few hours later the catheter was again used, and about three ounces of urine obtained, also containing much blood. The patient has recovered from the shock, and complains of great pain in both groins and in the hypogastric region, especially on pressure. No dulness can be detected over the abdomen. Poultices were applied to the thighs and abdomen, and half-grain opium pills administered every two or four hours. The vomiting continues.—6th: To-day there are evident signs of peritonitis, the tenderness being much more marked over the lower than the upper part of the abdomen.—7th: Some slight bruising of the abdominal walls over the bladder was noticed this morning. Urine was passed voluntarily for the first time to-day, and the use of the catheter discontinued. The vomiting has ceased. The urine still contains blood, but in less quantity than two days ago. The patient takes the pills now every four hours. The temperature has varied since the accident from 99·4° F. in the morning to 100·6° in the evening.—10th: Micturition is now very frequent (about every half-hour). In the evening the temperature rose to 102·2°, and the general condition of the patient became more serious. The tongue was dry, coated, and brown, the pulse small and feeble. Only small quantities of milk and beef-tea were taken.—12th: To-day the bowels were moved naturally for the first time since the accident. Micturition is still very frequent and almost involuntary. The urine is clear but contains a sediment of granular matter, chiefly phosphates. The temperature varies from 100° in the morning to 101° in the evening.—14th: To-day a tumour was noticed in the hypogastric region. Dulness was present from the pubes nearly to the umbilicus, and a distinct edge could be felt at the upper limit of the swelling, which was of the shape and appearance of a distended bladder. The tongue is cleaner, but the temperature is still about 100° to 101°. The urine is clear, and contains triple phosphate crystals.—15th: To-day phlebitis was noticed in the right leg, which by the next morning had extended to the femoral vein. The urine now contains pus, and is passed very frequently. During the next week the condition of the patient improved, the temperature remained between 100° and 101°, but more food was taken and the tongue cleaned. The phlebitis gradually subsided. On March 26th phlebitis occurred in the left leg, and the urine contained much pus and was very offensive.—31st: The tumour over the bladder, which had decreased, now began to increase, and deep fluctuation was detected over it. Pain in the abdomen was complained of on April 1st, and vomiting was very troublesome the following day. The temperature ranges from 100° to 102·6°; pulse 120; tongue dry and brown. The patient appears to be getting steadily worse.—April 3rd: Chloroform was administered this morning, and a two-inch incision made over the tumour, just above the pubes in the middle line. About thirty ounces of very foul-smelling purulent urine were evacuated, and a large slough of the size of the palm of the hand gently pulled out of the wound. The cavity was well flushed out with hot boracic acid lotion, a large soft indiarubber tube passed to the bottom of the wound, and brought over the edge of the bed to drain into a vessel on the floor. On exploring the cavity a perforation into the bladder could be felt. It was at the left and posterior part, close to the opening of the left ureter, and just large enough to admit the tip of the forefinger. The edges of the opening were rounded, thickened, and coated with phosphates. The operation lasted an hour and a quarter.—4th: Sickness troublesome all day. Temperature normal; pulse 120. The patient has rallied well from the operation. On the 5th phlebitis of the left brachial and axillary veins occurred; the sickness ceased to-day. The discharge from the wound is very thick, and contains a large amount of tenacious mucus.—8th: All the urine is still passed by the tube. The patient has much improved, and can now retain solid food. From this date convalescence was steady. The urine gradually became clear. The long tube was discontinued on May 8th and the patient removed to the sofa.—June 2nd: The wound has now almost healed. The urine still contains some pus and crystals of triple phosphates.—12th: Wound soundly healed. The patient is well, save that the urine contains a small quantity of pus and triple phosphates and is passed more frequently than natural. In August the patient was quite well and able to resume for some time past her usual habits. The urine could be retained for some hours, and no complaint was made of frequency of micturition.

CASE 2. *Intra-peritoneal rupture of the bladder; suture of the wound; death.*—A man, aged about thirty, was thrown out of his trap at 5.30 P.M., and his companion fell on his abdomen. The patient was not stunned, but for a few minutes felt unable to move; he then got into a passing trap and drove home, about two miles. On his arrival he walked upstairs and got into bed. I saw him at 9 P.M., and he then complained of severe pain in the hypogastric region, and of urgent desire, but inability, to pass urine. I passed a large silver catheter, but failed to draw off any urine. Dr. Lediard saw the case about midnight. The patient did not suffer from shock, had a warm moist skin, a full soft pulse, and had so little idea that he was seriously injured that he said he should go out again as soon as we had emptied his bladder. He assured me that he had passed urine freely about half-an-hour before the accident, and that he had never had any difficulty in micturition before. There was a distinct fulness above the pubes, and some dulness in the same region as if from a distended bladder. Under chloroform, about a pint and a half of bloody urine were drawn off by means of a lithotrity evacuator and aspirator. Next morning we found the patient sitting partially dressed in his dining-room; after some persuasion we induced him to return to bed, and again removed a quantity of urine by the evacuator. A catheter was first passed, but no urine could be drawn off. The patient now showed evident signs of a serious internal injury; his expression was anxious, his pulse small and thready, and his abdomen distended. The diagnosis was clearly a ruptured bladder. Mr. Page of Newcastle saw the case in the afternoon and, when the patient had been placed under an anæsthetic (a mixture of chloroform and ether), made an abdominal section. The bladder was found collapsed behind the pubes. There was a star-shaped rent about two inches long on the posterior surface opening into the peritoneum. This was sutured with catgut, but the patient died before the operation was completed. The peritoneum contained a large quantity of blood-clots and urine, and showed signs of commencing peritonitis.

Remarks.—The first case was perhaps as clear a case of ruptured bladder as could be seen, for almost all the symptoms in turn were present. The slough that was removed at the operation, when subsequently examined, was found to consist chiefly of mucus and phosphate crystals. The bladder must have ruptured close to the entrance of the left ureter. In the second case the history was certainly misleading, for if the bladder had been empty the injury present could not, I believe, have occurred. The patient had been drinking freely, and if he had recently emptied his bladder there was no doubt it must have contained a considerable amount of urine at the time of the accident. Shock was not present till some hours after the accident, and till then we thought that the bladder was merely contused and filled with clotted blood.

The above cases occurred in the practice of Dr. Lediard, F.R.C.S. Eng., Surgeon to the Cumberland Infirmary, and I am indebted to him for permission to publish them.

THE MECHANISM OF DELIVERY OF THE FŒTAL HEAD IN VERTEX PRESENTATIONS; ALSO THE PERINEUM IN LABOUR AND ITS MANAGEMENT.

By J. H. E. BROCK, M.D., D.P.H., B.S. LOND., F.R.C.S.,
HONORARY PHYSICIAN TO THE WESTMINSTER GENERAL DISPENSARY; LATE RESIDENT OBSTETRIC ASSISTANT, UNIVERSITY COLLEGE HOSPITAL, LONDON.

ALTHOUGH I have chosen "Mechanism of Delivery of the Fœtal Head" as the title of this paper, some of the remarks I have to offer will be applicable to all kinds of presentation. I propose, under mechanism, to consider "rotation" and "extension." As the former process takes place in exactly the same way and at the same place, whatever the presentation of the fœtus, the causes giving rise to it must be identical in every case. Having discussed "rotation," I shall take up "extension" of the head, described as invariably occurring during the birth in vertex presentations, in which the occiput has rotated forwards to the pubes, and shall adduce reasons for rejecting the idea that extension plays any part in the delivery of the head, pointing out at the same time that, did it occur, it would be a process of extreme disadvantage to the mother. In conclusion, the function of the perineum in labour having been noted, the method for preserving it, based upon observation of its behaviour and that of the head during parturition, will be described, and the results obtained in fifty cases of labour detailed. In attempting such a task as the above, I am fully aware that I shall be giving utterance to opinions directly opposed to those held by the authors of standard text-books of midwifery, and therefore contrary to ideas widely prevalent in the profession. Whether I shall succeed in proving my own case or no, I trust at least I shall be able to bring forward sufficient evidence to show that the explanations at present received of the mechanism of delivery will not bear a careful scrutiny, and for this reason are well worthy of being thought out afresh.

Rotation.—On reading the explanation of the mechanism of rotation as described in various text books of midwifery, one point has always forced itself on my attention—viz., that writers invariably account for the process by reasons which completely exclude the soft parts from any important share in the operation. Thus, to quote Lusk[1]: "In either of the occipito-anterior positions rotation is not difficult to understand. The convergent anterior inclined planes furnish smooth surfaces upon which the occiput glides downwards and forwards to the front. The rigid ischial spines direct the forehead to the sacro-sciatic ligaments, which determine the backward movement corresponding to that of the occiput in the front part of the pelvis." The smooth inclined planes of the pubes and the ischial spines are here assumed to be the prime factors in bringing about a change in the position of the head from the oblique to the antero-posterior diameter at the outlet; and with this view those of other authors substantially agree. To this explanation several objections suggest themselves: 1. Internal rotation of the head is effected by torsion of the neck of the child, the trunk hardly participating at all in the movement. The head is kept in this constant state of twist until after delivery, when untwisting or "restitution" takes place. This continued state of torsion requires that there shall be a constant force holding the head in position *nolens volens*. Even supposing the inclined planes of the pubes and the ischial spines capable of favouring rotation, they would certainly be incapable of opposing the necessary resistance to maintain the head in its distorted position, and prevent it unwinding. For between the ischial spines and the centre of the sacrum, into which the forehead rotates, there is a considerable space where the head would be free to move from side to side. If the ischial spines have any function at all they can only oppose a merely passive resistance to the forehead getting anterior to them, but they are utterly powerless to actively press it back into the sacrum and hold it there. If what I have said respecting the necessity for a constant force acting on the head to maintain it in the position of torsion be true of occipito-anterior presentations, it is still more true in the case of occipito-posterior positions, where the occiput in rotating forwards is twisted through three-eighths instead of one-eighth of a circle. Moreover, in breech presentations an actual twist of the trunk occurs at the outlet—a displacement which, considering the rigidity of the fœtal structures involved, and therefore the resistance that would necessarily be opposed to the movement, would, it seems to me, require something more than the favouring influence of the inclined planes of the pubes and the projection of the ischial spines to bring about and maintain. 2. In executing the movement of rotation, the head from lying in a diameter of 4¼ in.[2] (transverse) passes into one of 3⅜ in. (conjugate) at the outlet. It is only rational to suppose that any resistance which the bony parts might be likely to oppose, were they the sole agents to be considered, would be directed to the prevention rather than to the encouragement of a change by which the head, judging from the relative diameters of the bony pelvis, apparently assumes a position of disadvantage and deliberately hinders its own progress. Had the head only the bony pelvis to traverse, such an alteration in its direction certainly seems strange and unnatural. I shall presently have occasion, however, to point out that the movement, looked at by the light of the anatomy of the soft parts of the female pelvis, is not only not strange, but is the best possible that could be done under the circumstances.

In the causation of rotation Dr. Galabin[3] attributes much importance to the gradual narrowing of the pelvis from brim to outlet, and considers that the head rotates into the antero-posterior diameter, because the latter is the longest at the outlet, while the influence of the inclined planes, he believes, has been much exaggerated. The average relative diameters at the outlet Dr. Galabin gives as—transverse, 4 in.; antero-posterior, 3·5 in.; the latter being increased by extension of the coccyx to 4·5 in. Surely, it is scarcely fair to assume that the head by rotating forwards will exchange a pelvic diameter of 4 in. for one of 4½ in., seeing that the latter is not produced until the head is forcing its way through the lower pelvic strait after rotation is complete. To make such an assumption appears to me a *post hoc propter hoc* method of arguing. I presume it is agreed that rotation in the majority of cases takes place before the occipito-frontal diameter begins to come through the outlet, and therefore at a time when the antero-posterior diameter is still only 3½ in. I am borne out in this view by Lusk,[4] who says, "When, however, rotation is completed, the bi-parietal diameter (3⅜ in.), which is capable of sustaining a considerable degree of lateral compression, engages in the transverse diameter of the pelvis; at the same time the suboccipito-bregmatic engages in the conjugate. The latter, though measuring but 3⅜ in., may be extended to 4½ in. by the pressing backward of the tip of the coccyx." If anybody will make the experiment on a dry pelvis of putting the fœtal head through the outlet—first in the transverse and then in the conjugate diameter—he will quickly assure himself that, despite the narrowing which has taken place from brim to outlet, the advantage is still decidedly on the side of the transverse diameter, and that the gain to the head by veering round into the conjugate is, so far as the bony canal only is concerned, a very dubious one. 3. My last objection to the theory that the inclined planes of the pubes favour rotation forwards is this: From the moment that the head engages in the pelvis up to the time that it descends to the bony outlet it is in constant relation to the pubes. Now it is only right to infer that had the latter any marked directive action on the occiput, that action should continue during the whole time that the pubes remained in relation to the head. In other words, rotation on this hypothesis ought to keep pace with descent, and not, as actually takes place, be delayed till the presenting part has reached the outlet. Here the change in direction invariably occurs, and oftentimes suddenly, showing that the lower pole of the fœtus comes into relation with some more powerful rotatory force than the inclined planes of the pubes. What this force is can only be under-

stood by a reference to the anatomy of the pelvis, for which purpose I here introduce a diagram of a vertical section passing through the ischial tuberosities, and looked at from behind. The points in the drawing to which I wish to direct particular attention are the following:[5]—(*a*) The recto-vesical fascia, which forms, together with the levator ani, an oblique diaphragm across the pelvis, attached in front to the pubes, laterally to the obturator fascia, and behind to the ischial spines. The recto-vesical fascia, and with it the levator ani, may be looked upon as a septum passing obliquely across from the junction of the anterior wall of the pelvis with an imaginary ceiling to the junction of the posterior wall with an imaginary floor; while its lateral attachments are two

diagonals (the so-called white lines) drawn from the anterior and upper to the posterior and lower corners of the side walls. From its attachment to the side walls of the pelvis the recto-vesical fascia passes downwards and inwards to form sheaths for the bladder, vagina, and rectum. From this description it is evident that the floor of the pelvis presents two very marked slopes, one downwards and backwards, from pubes to ischial spines and sacrum; the other downwards and inwards, from the side walls of the pelvis to the various structures passing through the floor. I shall presently point out what I believe to be the significance of these two slopes in determining the movements of the fœtal head. (*b*) Between the pelvic diaphragm and the side wall of the pelvis on each side is the irregular wedge-shaped space, the ischio-rectal fossa, which at its base is an inch wide, and at its deepest part behind runs up the side of the pelvis for a depth of two inches. These spaces are completely filled with fat. (*c*) Covering the inner surface of the lateral walls of the pelvis are the obturator interni muscles. From all this the point clearly apparent is that below the level of the white line or upper insertion of the pelvic floor the transverse and oblique diameters of the pelvis become rapidly smaller and smaller, being encroached upon by the pelvic diaphragm and ischio-rectal fossæ to a far greater extent than by the gradual slope of the bony wall from brim to outlet; while, on the other hand, the antero-posterior diameter at the outlet preserves its length unaltered—that is to say, the conjugate at the outlet, from being the smallest diameter in the dry pelvis, becomes in the living body the longest. The pelvic diaphragm being composed of strong fascia and muscle, and the space between itself and the pelvic walls being filled in with fat, the extent to which the transverse and oblique diameters can be enlarged by compression and distension of soft structures must be comparatively slight.

The bearing of these anatomical points upon the path followed by the presenting part through the pelvis is evident. Taking the left occipito-anterior presentation for an example, we see that the head descends in the oblique diameter until it comes into relation with the sloping pelvic diaphragm. As pointed out above, the longest diameter of the pelvis available for the child now changes to the antero-posterior. The longest diameter of the fœtal head lying athwart the antero-posterior or longest diameter at the outlet, if further progress downwards is to be made, must turn into the conjugate; while the transverse or narrowest diameters of the fœtal skull accommodate themselves to the smallest or transverse diameters of the pelvis. In this rotation the occiput, being nearest the pubic arch and the lowest part of the advancing fœtus, naturally turns forwards in the line of the least resistance. It will further be seen that the state of twist of the neck of which internal rotation consists is not only brought about, but is kept up by the pressure which the sides of the pelvic diaphragm exercise. As the pelvic floor reaches down to the outlet the torsion of the head cannot be undone until it has escaped from the vulva. No theory purporting to be an explanation of rotation would be complete until it had also accounted for cases such as occipito-posterior presentations, in which the occiput, instead of taking the shorter course of rotation backwards, prefers the longer one of rotation forwards. The movement is usually accounted for by the statement that[6] "if the anterior wall (i.e., of the pelvis) be divided by a line drawn on a level with the lower margin of the symphysis, we find that in the superior division the general pelvic pressure diminishes from before backward, while below the line indicated pressure diminishes from behind forward." This greater pressure in front at the brim of the pelvis, acting at a superior mechanical advantage on the forehead, turns it backward, the occiput consequently coming forward to the pubic arch. No doubt the statement that the pressure in the lower part of the pelvis is greater at the back than in the front is true; but I am at a loss to understand on what the proof of the first portion depends. The upper plane of the pelvis being enclosed by a bony margin all round, I do not see how one portion of bone in front is capable of exercising a greater pressure than another piece of bone behind. Moreover, even supposing that this greater pressure really existed in front at the brim, it could manifest itself only as a passive resistance to the forward rotation of the forehead—a vastly different thing from an active driving force such as it must be if it is capable of pressing the latter back into the sacrum. Plainly, in order to fit in with a theory, passive resistance has been made to do the work of an active pushing force. Again, if it be correct that there is a difference in pressure between the anterior and posterior sections of the upper portion of the bony pelvis sufficiently great to drive the forehead back into the sacrum, it ought also to be capable of producing something requiring a very much smaller effort—viz., tilting up of the head towards the posterior shoulder. For on this hypothesis the anterior parietal bone must be constantly subjected to a greater pressure than the posterior, a result which can only terminate in one way—viz., by producing lateral obliquity of the head at the brim—a movement which it is pretty generally agreed does not occur in the normal pelvis.

It appears to me that the forward rotation of the occiput in occipito-posterior presentations may also be explained by appealing to the anatomical conditions which obtain in the pelvis. I have pointed out above that the pelvic floor presents two slopes—(1) downwards and inwards, narrowing the transverse and oblique diameters; (2) downwards and backwards from the pubes in front to the ischial spines and sacrum behind. In occipito-posterior presentations at the time that rotation of the occiput is going to occur forwards the head is in the following position: It is well flexed, the occiput is opposite the sacro-iliac articulation, and is the most dependent portion of the fœtus; while the forehead and face are turned towards the opposite acetabulum. As the uterus contracts the occiput, being the lowest part, is forced down first into the narrowest portion of the pelvis, and has the benefit at the outlet of the greater resistance behind opposing its rotation backward. On the other hand, the forehead, if it has to come forward, must move up the inclined plane of the pelvic floor, and therefore against a much greater resistance than it

[5] Godlee's Anatomy, p. 221.

[6] Lusk, p. 174

Digitized by Google

would do if it went backwards along the downward slope of the pelvic diaphragm. At the same time this resistance would be experienced along the whole length of the inclined plane, and, as it is directed against the long arm of the lever, would act at a greater mechanical advantage. The result is that as the uterus contracts and forces the child down, it is easier for the occiput to come forwards than the forehead, and consequently forward rotation of the former takes place. Should the head, however, not be completely flexed, the mechanical advantage on the forehead is lost, and the occiput goes back into the sacrum. After the birth of the head the vulva shrinks, the perineum retracts, and the anus contracts. On the pains recommencing, the shoulders descending in the opposite oblique diameter to the head are rotated forwards as they are forced down on the floor of the pelvis just in the same way as the head. Rotation of the shoulders always takes place on the pelvic floor, and usually rapidly.

(To be concluded.)

EPISTAXIS: AN EASY AND EFFECTUAL METHOD OF PLUGGING.

BY A. A. PHILIP, M.B., C.M. ABERD.

UNDOUBTEDLY plugging the nares by aid of Bellocq's cannula is an excellent method; but occasionally, especially in country practice, a Bellocq's cannula is not at hand, and some method easy, effectual, and effected by material always within reach, must be resorted to. Such a method I have found in the following. A piece of old, soft, thin cotton or silk, or oiled silk, about six inches square (a piece of an old handkerchief will answer) is taken, and, by means of a probe, metal thermometer case, or penholder, or anything handy, is pushed centre first, "umbrella" fashion, into the nostril, the direction of pressure when the patient is sitting erect being backwards and slightly downwards. It is pushed on in this fashion until it is felt that the point of the "umbrella" is well into the cavity of the naso-pharynx. The thermometer case or probe, or whatever has been employed, is now pushed on in an upward direction and then towards the sides, so as to pull more of the "umbrella" into the naso-pharynx. The thermometer case is now withdrawn. We have now a sac lying in the nares, its closed end protruding well into the pharynx behind, and its open end protruding at the anterior opening of the nares. If it be thought necessary, and is convenient, the inside of the sac may be brushed with some household astringent, such as alum solution, turpentine, &c. A considerable quantity of cotton wool is now, by means of the thermometer case, pushed well back to the bottom of the sac. Then, the thermometer case being held firmly against the packed wool, the mouth of the sac is pulled upon, and thus its bottom with the wool packed in it is pulled forward, and forms a firm, hard plug wedged into the posterior nares We may now pack the sac full of cotton wool, dry or soaked in some astringent solution. The mouth of the sac may now be closed by tying it just outside the nostril with a piece of strong thread; it is then trimmed by scissors and the ends of the thread secured outside.

The above method is easier than any I know when both nostrils have to be plugged. It might be suggested to oil the cotton or silk in order to render its introduction easy and to prevent it adhering to the mucous membrane, and to render it easy of removal; but I have never found any difficulty without the oil, as the blood renders the material wet and easy of introduction, while the oil does not facilitate removal, and may modify the effect of the astringents that may be used. The plug may remain *in situ* as long as any other nose plug. In removing the plug, open the mouth of the sac, and with small dressing forceps remove the cotton wool bit by bit; if there is bleeding simply syringe the sac with weak carbolic lotion or Condy's fluid and repack with clean cotton wool, or wool impregnated with some antiseptic. If there is no bleeding when the wool is picked out, gently pull out the sac; or if it be adhering to the mucous membrane, syringe in a little warm water, and it may then easily be removed. This method has many advantages. (*a*) It is easy, quickly accomplished, and effectual, and the materials are to be found in every house, and, indeed, about everybody's person (I have plugged in this manner, simply using a handkerchief, one part of which was used for the sac, and the other, torn into narrow strips, in place of the cotton wool); (*b*) no damage is done to the floor of the nose or back of the soft palate by strings &c.; (*c*) no disagreeable hawking, coughing, or vomiting takes place while the plug is introduced; (*d*) there are no disagreeable strings left hanging down the throat, causing coughing or sickness while the plug is in; (*e*) the plug can be removed gently without any force, so that no damage is done to the mucous membrane and no return of hæmorrhage caused. I employed this method frequently when in country practice, and do so now in bleeding after operation on the nares, and have always found it to be satisfactory. As the method has been of great use to me, and as I am not aware that anyone has spoken of it before, I take this opportunity of mentioning it, in the hope that it may be of use to some brother practitioner when confronted by an urgent case of epistaxis, and other means of plugging are not at hand.

Belfast.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

DIVER'S PARALYSIS.

BY P. W. BASSETT-SMITH, Surgeon R N.

WHILE on board H.M.S. *Penguin*, employed in surveying a part of the north-west coast of Australia, which was then an important centre of the pearl oyster fishery, several cases of this disease came under my notice now and then. The luggers contain about six men, mostly Japanese, occasionally Europeans, and are accompanied by a schooner which acts as a store and hospital ship. They are away many months at a time, sometimes a year; the food supplied was good. All the work was done in diving dress in depths of from ten to twenty-five fathoms, the period of submersion being often four or five hours. Cases of slight paralysis were common, coming on suddenly on removal of the dress, but generally recovering completely. The following is the worst case I saw:—

Sept. 5th.—Japanese, aged about thirty. Had been working in thirty-two fathoms (by all considered to be a dangerous depth) about three weeks ago; immediately on removal of the dress he became suddenly paralysed, and has been so ever since. His condition was one of great emaciation, free from pain, but very apathetic. Temperature 103°; pulse 120; tongue furred; complete paraplegia, with loss of control of bladder and rectum, and loss of sensation to the level of the umbilicus. There was a large deep bedsore over the sacrum extending from the tuber ischii on either side to the crest of the ilium above, with a thick, black, extremely offensive slough partially detached; it had eaten through skin, fascia, and gluteus maximus, and in places exposing the bone; there were also small sores over the ankles and knees. He had had a catheter passed twice a day, castor oil once a week, poultices and strong carbolic lotion to the sore, good diet, and port wine.—7th: No marked change. Temperature 103°.—8th: Refusing food; diaphragmatic spasm; moribund; died at 4 P.M.

This was no doubt a case of severe hæmorrhage into the lumbar centre of the cord, with subsequent myelitis, death being due to septic poisoning. The mate attending on him stated that he had been as bad himself with bedsores and paralysis for eight months; he now walks with a limp, but muscular power is fair and tissues firm, knee jerks increased. He said that a very bad sign is a localised swelling of the abdomen, from which, if allowed to get under the ribs, death is certain, and that they apply any pressure to keep it down, even "sit on it," probably a paralysis of intestinal muscles and collection of flatus. Those in charge told me that they

Digitized by Google

try to prevent men going down over twenty fathoms, but as they are paid by results it is very little use.

Admiralty Gulf, N.W. Australia.

CASE OF RUPTURED HEART.

By E. ROUSE ROUSE, M.R.C.S., L.R.C.P. LOND., L.S.A.

A. B——, aged fifty-two, a stout and plethoric-looking man, while playing football, suddenly and without warning fell down in a sort of faint, but soon recovered and continued to play until the close of the game, never at any time, however, really over-exerting himself. After the game was over, and while returning to the ward, he was again seized with a somewhat more severe fainting fit, and accompanied this time by severe pain in the cardiac region. I saw the patient about ten minutes after this, and found him somewhat collapsed, with an almost imperceptible pulse and very shallow breathing, and complaining of excruciating pain in the cardiac region. He was ordered to bed, hot fomentations were applied over the cardiac region, and he was given hot brandy-and-water at short intervals, followed by a sedative draught; he was then seized with violent sickness, and said he felt somewhat better. He was kept in bed for two days, and placed on milk and beef-tea; and as then his symptoms had disappeared, he was allowed up, but he was not to walk about the ward. He continued in this state up to the date of his death, exactly a week after, on which day he had another fainting fit, and died in less than five minutes. At the necropsy was found a complete rupture of the left ventricle, about half an inch in diameter. The pericardium contained twelve ounces of blood-clot, besides some blood mixed with a serous fluid. The heart substance was very friable and fatty degenerated, as were also most of the other organs.

The interest in the case arises from the fact that the man lived exactly seven days after the date when we may assume the rupture partially occurred, or otherwise how are we to explain the severe symptoms complained of? But it is difficult to understand how he lived so long, unless we presume that, on the day when he was seized with his severe symptoms, the rupture was incomplete, or so small as not to allow the escape of blood into the pericardium, but that on the date of his death a sudden exertion or an increased pressure of blood ruptured more completely the previous injury, and as a consequence the immediate rush of blood stopped the heart's action, which undoubtedly was the cause of death. I should be glad to hear of anyone who has had similar cases, though I find in Bristowe's Medicine patients having lived a few hours or even a few days, but never as long as a week. The above case is, I think, of sufficient interest to be worthy of record.

Colney Hatch Asylum, New Southgate, N.

HÆMATOMA OF VULVA POST PARTUM.

By FRED. W. MANN, M.B.,

LATE HOUSE SURGEON TO THE SIMPSON MEMORIAL AND MATERNITY HOSPITAL, EDINBURGH, ETC.

MRS. H——, residing in Huddersfield, aged thirty-four years, multipara (married sixteen years), seven labours and three miscarriages. The patient always enjoyed good health during her married life, is above an average-sized and a strong-looking woman. Last miscarriage four years ago; youngest living child nearly three years old; last menstruated about Sept. 5th, 1890. All her labours, with the exception of the first, were pretty easy, the last being very easy. I was called to see Mrs. H—— on Sunday, May 17th, 1891, at 8.30 P.M. On vaginal examination the following was made out: Head at pelvic brim, os well dilated, and membranes almost down to vulva. I ruptured the membranes, and the head descended and presented; in about an hour the labour was completed without any further assistance. I inspected the perineum, which I invariably do, and it was not in the least injured. I gave her a drachm of ergot by the mouth, washed and bound her up, and after taking the pulse, which was about 90 per minute, left. About 3 A.M. the same night the husband came for me, and said that something had come down; he thought it was the womb. I refused to go, being absolutely sure the uterus could not by any possibility have become prolapsed. After a little while the daughter came for me crying, and said that her mother was dying. On my arrival the patient was perfectly blanched, sighing, gasping for breath, vision obscured, and picking at the bedclothes. On visual examination a swelling the size of a man's skull was observed between the thighs, which was a hæmatoma of the left side of the vulva. I applied a cold antiseptic cloth, and went for Dr. Macgregor, whose patient she was, and whom I was assisting at the time. We went back together immediately, to find that the patient had burst the sac and was lying in a pool of blood. Dr. Macgregor examined her quickly, and confirmed my diagnosis. He then increased the rent, turned out the clots, syringed the cavity with hot antiseptic lotion, and plugged with sterilised gauze. Brandy and soda-water and milk were freely administered. The plug was removed twenty-four hours after, and not replaced. Subsequently she was syringed out by me twice daily with sublimate for ten days, and then continued it herself. She recovered without a bad symptom, and without a rise of temperature.

Remarks.—The following are worthy of note: The easy labour, the bursting of the tumour, antiseptic efficiency in midwifery, and recovery. My apology for publishing the case is its rarity, and its occurrence oftener in easy labours than those in which instruments are used.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

ST. THOMAS'S HOSPITAL.

EXCISION OF THE ILEO-CÆCAL VALVE FOR CARCINOMA; SUBSEQUENT OPERATIONS FOR FÆCAL FISTULA; RECOVERY.

(Under the care of Sir WILLIAM MAC CORMAC.)

THE case we here record is one which presents many features of interest. Although chronic intussusception is more common in adults than in children, and in the situation in which it appeared here than in other parts of the intestine, it is rare to find a malignant growth forming part of the tumour produced by the intussusception and apparently the cause of it. The cases of resection of intestine for malignant disease hitherto recorded are but few, and of these success equal to that obtained by the operations in this patient has seldom been achieved. The question as to the best method of treating malignant disease involving the large intestine is one which must be decided at the time the individual sufferer applies for relief. Sometimes the symptoms of obstruction are too urgent, the general condition too bad, to permit of any prolonged operation; the growth has too many adhesions to surrounding parts to allow it to be brought to the surface, or there are considerable secondary deposits. In these cases the formation of an artificial anus is desirable. When the circumstances are as favourable as they appear to have been here, the operation of resection presents advantages offered by no other method. It will more especially meet with favour in similar cases should it ultimately appear that immediate suture after the resection can be done with equal or greater safety than the resection, formation of artificial anus, and the serious operation for the closure of the latter. Hahn's statistics were in favour of the performance of the operations in two stages. Senn has recorded two cases of resection of the cæcum for carcinoma in which he employed his decalcified bone plates. One of these was a success; the other died from ulceration of the intestine. We hope it will be possible to give the ultimate result of the operations on this patient. For the notes of the case we are indebted to Mr. H. B. Robinson, late resident assistant surgeon.

E. O——, aged thirty-six, a blacksmith, was admitted into the hospital on Nov. 29th, 1890. There was no history

Digitized by Google

of cancer in the man's family, and until the present illness the patient had enjoyed good health. Five months before admission he was suddenly seized with violent griping pain in the umbilical region, which lasted for one day; this was followed by a similar attack one month later. The attacks then became more frequent, occurring every week, and occasionally oftener. During these attacks, which came on without any obvious cause, he felt a lump in the right inguinal region, which enlarged towards the epigastrium and dispersed with gurgling. The motions passed during the attacks were of a dark colour, and sometimes contained blood. Sometimes during the attacks he suffered from diarrhœa. In the last four months the man had lost fourteen pounds in weight. The abdomen on examination proved to be thin and retracted. A lump was to be felt in the right iliac region, tender on palpation, which produced slight gurgling. On Dec. 2nd, 3rd, and 4th he had attacks of pain with increase in size of the tumour. On the last date there were considerable diarrhœa and copious discharge of blood.

Under chloroform, on Dec. 7th, a slightly curved cylindrical tumour, with concavity downwards, elastic and resistant, was felt. Two-thirds of the growth were to the right of the middle line, and its lower border was on a level with the umbilicus. The swelling could be moved about with the fingers, mostly in a direction transverse to the long axis of the tumour.

Dec. 10th.—Abdominal section was performed by Mr. Sydney Jones, by an incision about five inches long in the linea alba. The tumour was found to be an intussusception of the ileo-cæcal form. This was easily reduced, except close to the valve, where firm adhesions had formed, which had to be broken down. The valve itself was greatly thickened, and the lips were covered with papillomatous growths. The cæcum, with adjoining parts of large and small intestine and a V-shaped piece of mesentery, was resected, and the open ends of the intestine were attached to the abdominal wound to form an artificial anus, the opening into the large intestine occupying the higher position. The growth was examined and pronounced by Mr. Shattock to be carcinoma.

From this operation the man rallied well and made satisfactory progress. On Dec. 25th he had two syncopic attacks, but they were not repeated, and nothing further retarded his convalescence. Owing to the very great annoyance from the fæcal discharge from the artificial anus and from the extensive excoriation of the surface produced by it, and from the absence of any return of the growth, it was decided to restore the lumen of the bowel. This was done on Feb. 20th, 1891, after having well flushed out the intestinal tract with warm boracic fluid.

The two ends of the gut having been well washed with boracic acid, and the surrounding skin with 1 in 5000 perchloride of mercury, two small sponges with strings attached were inserted in the openings into the intestinal canal. An incision was made along the old linear cicatrix above and below the openings, and the two wounds thus formed were joined by incisions on either side of the artificial anus. By careful dissection the ends of the intestine were separated from the adhesions, the small intestine being first freed, and subsequently the large. Two stout ligatures were now tied round the ends just external to the sponges, to prevent any escape of their contents, and after further separation each end was clamped on the proximal side of the sponge, and the latter withdrawn. The ends of the intestine were now trimmed up, so that the attachments of the mesentery corresponded with their cut ends. The cut edges of the mesentery, after the insertion of Senn's circular indiarubber ring into the small intestine, were brought together with fine silk interrupted sutures. An attempt was now made to invaginate the small into the large intestine (Senn's circular enterroraphy), but this did not succeed very well, especially at the posterior part, and the circular ring tended to collapse. Lembert's sutures were accordingly used to complete the junction until the two ends were firmly united all round. During the suturing a sponge was placed in the abdominal cavity, to prevent any contamination by fæcal matter, but nothing whatever escaped from the intestine. The clamps were now removed; and the intestinal loop having been washed over with a 1 in 5000 perchloride of mercury solution, was returned into the abdominal cavity so as to rest just beneath the wound. The external incision was then closed. At 11 P.M. he complained of thirst; slight hiccough. At midnight his pulse was 80, and temperature 97·4°. Tongue dry and parched, and he was ordered to rinse it out with water. No discharge from wound. Rather restless. A quarter of a grain of morphia given hypodermically.

Feb. 21st.—8 A.M.: The patient slept fairly well after the injection; temperature 97·6°; he complained of slight pain in the abdomen. He was given a teaspoonful of water to drink from time to time. 8 P.M.: Had another injection during the day, as pain is still present. Dozed on and off. Passed twelve ounces of urine. Temperature 99·2°; pulse 86.

22nd.—8 A.M.: He had a much more comfortable night, having slept fairly well, and very little pain. Not so thirsty. Temperature 99°; respiration regular. Sixteen ounces of urine were passed, loaded with lithates. Has passed flatus. 8 P.M.: Had some sharp pain at intervals during the day, but slept on and off. Allowed small quantities of barley water, beef-tea, and brandy. Temperature 99·8°; pulse 80. There is no pain this evening.

23rd.—He has been restless and thirsty during the night. Temperature 98°. 8 P.M.: Has been coughing during the afternoon, and been restless and irritable, complaining still of thirst. Slept at intervals. Temperature 100·8°; pulse 84. Passed twelve ounces and a half of urine. No complaint of pain.

24th.—8 A.M.: The patient has had a very good night, sleeping most of the time, without any pain. Temperature 98·4°. 8 P.M.: Fretful and restless, complaining of pain and of the tightness of the bandage. Some cough. Temperature 100·6°; pulse 86. Tent and steam-kettle ordered. At midnight the temperature was 102°, with profuse sweating.

25th.—8 A.M.: He complains of some pain in the left side. Temperature 100·2°. Bowels acted slightly (about three ounces) for the first time, and has passed large quantities of flatus. Complains of being in pain in the lower part of the bowel. 8 P.M.: Bowels slightly open again. Very comfortable during the day. Temperature 99·4°. Ordered one drachm of port wine every two hours.

26th.—Good night with no pain. Temperature 99°. 8 P.M.: Temperature 100·6°; pulse 100. Bowels opened at 6.30 P.M., and about three ounces of partially formed motion passed. At 10 P.M. a bad smell was noticed from the wound, and on the dressings being removed they were found to be saturated with dark fæcal matter. The sides of the wound had separated about half an inch, and at the bottom, about the middle of the incision, there was a small opening into the gut, from which fæces came out.

27th.—Temperature 98·4°. Passed a good night. In the evening slight action of the bowels per rectum. Temperature 101·6°.

28th.—Very restless night; complaining of pain in the right side. The stitches were all taken out and strapping applied. Fæcal discharge from fistula free. For the last two days milk has been given. Temperature 101·4°.

March 2nd.—Not quite so well owing to slight pneumonia. Temperature 102·4°. Passed a motion per rectum.

3rd.—Better, but temperature still up to 101°. Another motion per rectum; discharge from fistula about the same.

4th.—Two more motions per rectum. Temperature only 99°, and much better.

7th.—During the last twenty-four hours the patient has passed more per rectum. The fistula, however, still discharges, but in less degree. The wound remains open, and at the bottom of it a tongue of granulations protrudes towards the right side, at the apex of which is the opening of the sinus. The indiarubber tube has not yet been passed. Temperature normal.

16th.—Since the last note the patient's abdomen has been tightly strapped. Very little has come from the fistula, which is smaller, and the wound itself has healed considerably. He has had at least one action of the bowels per diem. Cough practically gone. Some œdema of right leg.

30th.—Fistula very much smaller, the everted mucous membrane filling the opening. There is very little fæcal matter passed through it.

April 7th.—Fistula still smaller. Strapping left off.

15th.—A plastic operation was done for the closure of the fistula. Sir William Mac Cormac marked out two flaps, one on the left side extending upwards for three inches and a half from close to the fistula, and being about one inch wide, and the other on the right side of equal size, but pointing downwards. After raising the flaps, which consisted of skin and subcutaneous tissue, the upper or left flap was brought across the abdomen and placed below the lower or right flap. The edges of the flaps were then sutured together,

Digitized by Google

as well as the edges of the wounds from which they had been raised. After the suturing the fistula was completely covered in. Iodoform dressings were used.

16th.—No fæcal matter has made its appearance. Some slight serous discharge from the wounds. The right flap looked somewhat blue. Patient very comfortable.

17th.—Since the operation there has been no action of bowels. A good deal of fæcal matter has made its way between the lips of the flaps. Right flap still discoloured.

21st.—Sutures removed from wounds from which the flaps were raised. Skin separating from the right flap, the edges of which are blue.

24th.—Remaining stitches taken out. About one inch of the right flap is sloughy, but has not yet quite separated. Fæcal matter still passing. Rest of the wound appears very healthy.

28th.—Slough separated.

30th.—No fæcal escape for the last two days.

May 1st.—As the right-hand flap had sloughed along its upper or left-hand margin, and thus was giving no support over the position of the fistula, the skin above the flaps was dissected up for a short distance, and its edge brought down and stitched to the upper edge of the right flap remaining.

5th.—All stitches removed.

11th.—Slight escape from fistula.

19th.—No fæcal matter passed since the 16th. Allowed to get up.

29th.—On coughing last night a little fæcal matter escaped from the fistula, and the same happened this morning.

June 1st.—Discharged from hospital with slight fæcal discharge from time to time.

About six weeks after leaving hospital the patient wrote to say that for the last few weeks there had been no discharge, and that the wound was quite soundly healed. In October he was doing his work as a blacksmith without any inconvenience or sign of return.

Remarks by Mr. ROBINSON.—This case is a further proof that the chances of obtaining a successful result after resection of the bowel are considerably increased by performing a secondary operation for uniting the ends. Here there was the additional advantage that the large bowel from its inactivity had diminished in calibre, thus permitting more perfect union of the ends. Although Senn's indiarubber tube was tried for the approximation, its sole use proved inefficient for perfect junction, as it would collapse, and it was necessary to have resort to Lembert's method of suturing. In spite of this, the gut unfortunately gave way, but luckily the escape was from the wound. The fistula remaining behind was ultimately closed by a plastic operation in which the whole thickness of the skin was raised, allowed to thicken, and then transplanted.

ROYAL ALBERT HOSPITAL, DEVONPORT.

A CASE OF FOREIGN BODY IN THE BLADDER AND URETHRA.

(Under the care of Mr. J. HARLEY GOUGH.)

IN THE LANCET of Nov. 7th, 1891, p. 1039, Mr. Selby W. Plummer records a case of foreign body in the bladder and urethra, which was treated at the Durham County Hospital. A somewhat similar case occurred recently at the Royal Albert Hospital, Devonport. In both instances the foreign body, a long bonnet pin, was successfully extracted by perineal section. In our remarks we referred to cases[1] of similar injury in which it was found possible to remove the foreign body after manipulation; the point, being made to project in the perineum, was pulled out until the head prevented further progress, then turned, the head pushed forwards through the meatus, and the pin extracted.

J. T——, aged fifty-one, a big, fine-looking man, came to the out-patient department on the afternoon of Oct. 5th, 1891. He said that the night before, when under the influence of drink, and for reasons he would not explain, he passed a long bonnet-pin head first down his "pipe" and could not get it out. Owing to some feeling of discomfort and pain after micturition he sought relief at the hospital. On examination nothing could be felt in the penis, but deep in the perineum a prominent point could be made out. The scrotum was pulled up, and without an anæsthetic an incision was made over it, and the point of the pin exposed. This was seized with a pair of Spencer Wells' pressure forceps and forcibly drawn forwards till the beaded end was held by the urethra. The urethra was incised and the pin extracted. A No. 10 gum elastic catheter was passed down the urethra into the bladder and tied in, and the patient put to bed. Two days later the catheter was replaced by another. On the fourth day the wound in the perineum had healed by first intention, and on Oct. 10th, 1891, the patient was discharged cured. The pin was an ordinary blue bonnet one, five inches long, with a black-beaded head.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Enchondroma following upon Multiple Exostoses.—Dermoid Cyst attached to Omentum.—On Suppuration.—Rupture of Spermatic Vein simulating Melanotic Sarcoma.—Congenital Malformation of Heart.—Carcinomatous and Adenomatous Mammary Growths.—Mucous Cysts of Ureters.

AN ordinary meeting of this Society was held on Feb. 2nd, the President, Sir George Humphry, in the chair.

Dr. GRIFFITHS of Cambridge brought forward a specimen of Enchondroma following upon Hereditary Multiple Exostoses. He showed the bones of the left lower limb of a man aged thirty-one, on which there were many exostoses of the usual kind, and one large enchondroma on the upper end of the tibia. The enchondroma had taken a rapid growth for nearly a year, and latterly had given rise to pain and much inconvenience from its bulk. There were other exostoses on the right lower limb, but there were none on the trunk and upper limbs, where the only detectable change was thickening and nodulation at the epiphysial lines of the lower end of the radii, upper end of the humeri, and inner ends of the clavicles. The affection ran in his father's family—one brother had "lumps" and a deformed arm; another brother and two sisters, who took after their mother's family, remained quite free. The father had many lumps, on the lower limbs especially; also his grandfather, who died from the enlargement of one of the lumps, and a paternal aunt, who had lumps and a deformed arm. Dr. Griffiths then referred to similar published cases, and expressed his opinion that it was as yet difficult to determine the real etiology of these growths.—The PRESIDENT remarked that the patient exhibited a combination of two kinds of cartilage growth. There was a chondro-exostosis of usual characters, but remarkably multiple and hereditary. This was associated with a cartilage growth, which had no bone formation at all; it encircled the bone as fibromas often did, and did not spring from a single point. These chondromata were not commonly hereditary. This patient thus showed both chondro-exostosis and subperiosteal chondroma, but he presented no instances of the true enchondroma of the phalanges. It was interesting to note that there was a condition present which seemed to be some approach to rickets, but there was nothing to explain the ankylosis of the tibia and fibula at their lower ends.

Dr. GRIFFITHS also exhibited a Dermoid Cyst which was attached to the lower and free border of the omentum. He regarded this as probably having had origin in one or other ovary, become pedunculated and attached to the omentum, and then ultimately it became severed from its original connexion.—The PRESIDENT said that the tumour gave way during the operation, and the contained fatty material flooded the peritoneum. It had only increased in size of late, though probably it was of congenital origin. Though these tumours were occasionally found in the peritoneum, it was difficult to believe that they were formed in connexion with the ovary. He referred to a case in which hair, teeth, &c., had been found in a woman's bladder; he removed them successfully, but he could not conceive how they had got there. He believed that these tumours occurred only in women, and if that were the case it was in favour of their ovarian origin.—Mr. W. G. SPENCER asked

Digitized by Google

if it were necessary, in order to account for these dermoid cysts, to believe that they were developed from epiblast invaginated from the surface. The epithelium of the ovary and also that of the Woolfian body and its duct was of cœlomic origin, and therefore mesoblastic, though of course it must have been primarily derived from either the epiblast or the hypoblast. If dermoids could thus arise from cœlomic epithelium, it was quite possible for them to spring from the omentum direct, the covering of that structure being of similar origin.—Mr. SUTTON said that dermoids inside the peritoneal cavity only occurred in women. They had been seen in the pelvis in both men and women, but they were always beneath the peritoneum. Dermoids of the omentum had been, so to speak, "caught in the act" of shifting their habitation from the ovary to the omentum, and had been found with a slender attachment to the ovary and a firm adhesion to the omentum by Knowsley Thornton, Doran, and himself. Non-dermoid tumours had also been seen shifting their position from the ovary to the omentum. These facts were more convincing than arguments founded on strange fancies as to the origin of epithelium. He asked the President if the ovaries and tubes of this case were examined at the time of the operation.—Dr. GASTER referred to the case of a female child aged eight, who was operated on at the Children's Hospital at Bucharest by Dr. Rominceano. There had been for some time a fistula in the right iliac region, and on abdominal section a dermoid cyst of the size of a large orange was found in the peritoneum, in the right side; it was safely removed. The child died two days after the operation and at the necropsy, which was carefully performed, the ovaries were found quite normal.—Dr. GRIFFITHS, in reply, said that the tumour was attached to the under-surface of the omentum, and did not appear to be formed in its substance.

Mr. S. G. SHATTOCK read a paper on the inadequacy of the current terms applied to Suppuration, with a note on Peptone in Pus. The author contended that the time had arrived for a revision of the terms at present in use as applied to suppuration. The terms "suppuration" and "pus" were purely anatomical, and included things quite different in their etiology. Setting aside larger questions, the process of acute suppuration could etiologically be distinguished from other forms, and that it was as specific in nature as tuberculosis or syphilis was now well established by experiment. Koch's four postulates in this case were all capable of fulfilment, whilst the doctrine was confirmed by the check experiments of introducing aseptic chemical irritants beneath the skin of animals, and which, if the animals were healthy, produced inflammation but not suppuration. A strict parallel might be drawn between tuberculosis in its different manifestations and acute suppuration. Corresponding with the localised tubercular lesion was acute abscess; "diffuse suppuration" represented the results of local infection when the tissue elements failed to cope with the virus. The secondary glandular infection in tuberculosis and the glandular abscess common after suppuration at a distance were parallel, whilst pyæmia was the counterpart of generalised tuberculosis. To bring out the facts, the term "pyosis" was suggested by the author; generalised pyosis would be what is termed pyæmia, glandular pyosis the secondary glandular infection, whilst the acute abscess or acute suppuration of a wound would be pyosis in a local form. The author afterwards recounted some observations on the presence of peptone in the pus of acute abscesses. He had examined thirty cases. The simplest method of showing this was to shake the pus with half its bulk or less of saturated solution of ammonium sulphate and then add crystals of the same salt to saturation; then filter. If a drop of copper sulphate solution be added to the clear filtrate no precipitate is produced, for the ammonium sulphate precipitates all the proteids except peptone; and on adding excess of solution of caustic potash a dense white precipitate of potassium sulphate is thrown down. On this subsiding the pink colouration of the clear supernatant fluid, though usually pale, shows the presence of peptone. He had been able by dialysing pus to show the same. The peptone, of all the proteids, alone passes through the dialyser, and may be shown in the water by the biuret reaction, sulphate of copper solution, and solution of caustic potash. For the separation of the albumoses Sydney Martin's method was necessary, and if properly carried out the demonstration was easy; the pus was shaken with excess of alcohol, and kept several weeks in a stoppered bottle, filtered, the residue on the filter dried and rubbed up with distilled water and filtered. Albumoses and peptone were alone dissolved. The addition of ammonium sulphate to the filtrate produced a precipitate of albumose, and the filtrate from the latter gave the biuret reaction of peptone. The presence of albumose and peptone in pus was not peculiar to the action of pyogenic microbes. Martin had shown both in the alkali albumen in which he had grown bacillus anthracis.—Dr. HUNTER said that undoubtedly the peptone was formed by the agency of the organisms in the pus, and it was possible to give even a clearer demonstration of this fact; for if the ferments were isolated from the organisms they would still form peptones in albuminous fluids. This explained the reason of localised or diffuse inflammation occurring after primary infection. If the organism were one which gave rise to a ferment of great peptonising power, then the tissues would undergo rapid solution, and the lymphatics being quickly blocked the inflammation would remain localised; but if, on the other hand, the organism produced a ferment of low peptonising power there was but little solution of tissue, the lymphatics remained open, and the inflammation spread.—Dr. LEE DICKINSON said that he had examined several specimens of pus from pleural empyemata, and had always found the albumose to be more abundant than the peptone; but this might be possibly because the peptone was rapidly absorbed from the pleura. Dr. Martin had found very little peptone in the fluid in which anthrax bacilli had been cultivated.—Mr. SHATTOCK, in reply, said that the amount of peptone in all his specimens was very small, being indeed a mere trace, and the amount of albumose was much larger.

Mr. W. G. SPENCER exhibited the Right Testis and Spermatic cord of an Infant, the epididymis and lower part of the cord having been surrounded by, and infiltrated with, blood-clot. Microscopic specimens showed, in addition, large spermatic veins in the midst of the mass. It was taken from a child fourteen days old, who was brought to the Westminster Hospital with a tumour in the right scrotum. The affection had been noticed three days after, but the mother could not say whether it was present at birth. The birth was normal, and there were no other indications of injury or of disease. The swelling involved chiefly the back of the testis and the lower part of the cord. The skin over the swelling was adherent, and bluish-black in colour. Beyond the swelling the skin was normal, without sign of bruising or of inflammation. On puncture it proved to be solid in consistence, some blackish fluid escaping. Mr. Macnamara saw the case, and it was agreed that the disease appeared suspiciously like a melanotic sarcoma. On incision the surface of the section looked black; the testis and the cavity of the tunica vaginalis were healthy, and there was no sign of blood-clot in a cavity. The diagnosis of melanotic tumour seemed correct, and castration was performed, which was followed by rapid healing. But on microscopic examination by Dr. Hebb, the tumour was found to have been due to an infiltration of the epididymis and cord by extravasated blood. Concerning the exciting cause of this condition he had no evidence. Light was thrown upon the predisposing conditions by a paper of his on the Origin of Varicocele in vol. xl. of the Society's Transactions. In it he described the large size of the veins, which, at first belonging to the more vascular Wolffian body, were transferred later on to the less vascular testis. The veins accordingly tended to become relatively less in size and number by a process of atrophy, which affected the right more than the left side. But these veins were still relatively large and numerous at birth, as could be seen in the drawings attached to the paper referred to as well as in the microscopic specimens shown.—Dr. HERBERT SPENCER remarked that hæmorrhages in the testes and spermatic cord were not at all uncommon in stillborn children, especially in those in whom there had been breech presentation. Hæmorrhages were also not uncommon in other viscera. He had brought forward the results of over 300 post-mortem examinations in a paper which was read before the Obstetrical Society, and in which he had referred to the hæmorrhages into various organs. Important points in connexion with the hæmorrhages were the question of future impotence and of the prevention of the descent of the organ in cases of undescended testis.—Mr. W. G. SPENCER replied that although aware of hæmorrhages in these regions in breech presentations, in the case under discussion the tumour was so hard and firm that it was believed to be of malignant nature, and hence the castration.

Dr. NORMAN MOORE showed a Congenital Malformation

Digitized by Google

of Heart from a boy aged five months, who had been under observation since three weeks of age. The aortic arch was large, and arose from an abnormally large left ventricle. A mitral valve opened into this from a left auricle of about normal size. The foramen ovale was widely open, and the right auricle was of double the normal capacity and thickness. There was no actual tricuspid valve, but only an opening the size of a pin, which led into a right ventricle not larger than two pins' heads. From this issued a very minute pulmonary artery without valves at its orifice. This doubled in width near the ductus arteriosus, which was patent. The circulation was carried on by the single ventricle, the pulmonary blood stream being directed through the ductus arteriosus from the aorta. The blood from the hypertrophied right auricle was driven into the left auricle, and thence through the wide mitral valve into the left ventricle. The blood currents were all of them mixed. The child was deeply cyanosed, but had no clubbing of its fingers or toes. It was always very short of breath and never sucked well. A first and second heart sound were audible, but no murmur.

Mr. G. B. M. WHITE showed a Mamma containing Adenomatous and Carcinomatous Tumours from an unmarried woman aged sixty-one. A tumour had been noticed in the right breast for about two years. After removal, besides the carcinoma, two adenomata were found in the same breast lying close to and beneath the main tumour. At the same time a small adenoma was removed from the left breast.

Mr. J. JACKSON CLARKE showed the Kidneys, Ureters, and Bladder of an old woman who was moribund when admitted into St. Mary's Hospital under Dr. Lees. A large hæmorrhage in the right cerebral hemisphere was found. The arteries at the base of the brain were extremely atheromatous. Her history could not be obtained. The left kidney was hydronephrotic. There were a few small cysts placed close together in one of the pyramids. There were cysts in a dilated calyx and in the pelvis, and very numerous cysts of the average size and the colour of hemp-seed in the upper half of the ureter. The right kidney contained one subcapsular cyst; the right ureter was normal. In the bladder there were cysts at the ureteral orifices and at the neck. The cysts in the ureters contained the large cells, which have been supposed to be coccidia. Mr. Clarke's sections showed all stages of development of the ureteral cyst, of which the smallest contained detached epithelial cells, only slightly œdematous. Mr. Clarke regarded the larger cells found in the older cysts to be likewise epithelial cells, which had undergone further degeneration. There were none of the large cells in the cyst of the kidney and of the bladder. Mr. Clarke thought that possibly some of the cases of hydronephrosis which had been cured by massage might have been due to ureteral cyst, which easily collapsed. He thought a more general use of the cystoscope might lead to the recognition of similar conditions during life, and that then examination of the urine might reveal some chemical irritant as the cause of the condition.—Mr. BLAND SUTTON referred to Mr. Silcock's case, in which the cells had continued to grow after the tissue had been placed in a hardening solution of weak chromic acid. It was impossible to conceive of tissue cells doing so, though quite conceivable of psorosperms.—Mr. GRIFFITHS asked Mr. Clarke whether he knew if cysts of any size could arise from cystic degeneration of a single cell.—Mr. CLARKE replied in the negative, and expressed himself as still unconvinced, so far as his own specimen was concerned, that the cysts in question were due to the presence of parasitic psorosperms.

The following card specimen was shown:—Mr. J. J. CLARKE: Fibroma of Small Omentum.

OPHTHALMOLOGICAL SOCIETY.

Tuberculosis of the Iris, Suspensory Ligament, and Retina.—Etiology, Prognosis, and Treatment of disseminated Dot Cataract.

AN ordinary meeting of the Society was held on Thursday, Jan. 28th, Mr. Henry Power, F.R.C.S., President, in the chair.

Mr. R. L. KNAGGS (Leeds) communicated a paper on a case of Tuberculosis of the Iris, Suspensory Ligament, and Retina, which was read by the secretary. The patient, a boy aged nine months, had iritis of a quiet type associated with fourteen to twenty white nodules in the iris. Those in the lowest part of the anterior chamber grew most rapidly and coalesced, forming a large yellowish mass, which produced a considerable growth at the sclero-corneal margin. The eye was excised, but the child died seven weeks later from tubercular meningitis. Sections of the eye showed that the iris had been transformed into a tuberculous mass, in which were many distinct miliary granules. The growth had bulged and thinned the outer tunic of the eye, had penetrated the uveal pigment layer at a point just in front of the ciliary body, had passed through the suspensory ligament, and had been stopped abruptly at the hyaloid. The canal of Petit was filled with inflammatory exudation, and contained several tubercles in which giant cells were well marked. The disposition of the suspensory ligament did not seem to have been altered by the tissue in which it was embedded. In the lens were cell spaces filled with inflammatory cells, and in the retina there was an inflammatory focus situated between the nerve fibre layer and the pigment layer, the latter being quite unaffected. The case was recorded not only as a contribution to the literature of tubercular iritis, but because of the bearing it had upon questions connected with the suspensory ligament. Drawings of the pathological conditions were exhibited.

Mr. CHARLES WRAY (Croydon) read a paper on the Etiology, Prognosis, and Treatment of *disseminated* Dot Cataract. After commenting on the narrow limits of the literature of the subject, he pointed out that the commonest form of this affection was characterised by the presence of large numbers of very thin, punctiform opacities, generally less than ·5 millimetre in diameter, symmetrically arranged in the substance of the lenses. The opacities were, as a rule, most numerous towards the equator of the lens, and were at times quite absent from the periaxial parts. Sometimes, in addition to the dots, there were streaks of opacity arranged without reference to the anatomical structure of the lens; occasionally the dots were so minute, and situated so peripherally, as to be overlooked unless very carefully searched for. The following varieties of dot cataract had been noticed:—(1) The simple form, as above described, occurring in young subjects, with no other changes suggestive of lens degeneration; (2) the simple form, complicated by the presence of opaque streaks arranged without reference to the anatomy of the lens; (3) the last mentioned further complicated by the presence of vacuoles; (4) the above conditions with degenerative changes suggesting ordinary advancing cataract. The affection was most easily recognised in childhood; in later life it might be mistaken for developing senile cataract. Nothing in the history or condition of the patients seemed to account for the lens changes; the simplest view was that they were merely transmitted structural peculiarities, like the white dots found on the finger nails. This simple explanation seemed the more probable, since in each case in which the condition was found in the offspring it was observed in the mother. In regard to prognosis, two points were noteworthy—the non-deterioration of vision in the parents, and the presence of the dots unchanged in one patient who had advanced nuclear (senile) cataract. In only one instance had the question of treatment to be seriously discussed, and in this, the vision with correcting glasses being equal to the patient's requirements, no active interference was advised. If in any case the sight were not sufficient for the requirements of the individual, the rules applicable in the treatment of lamellar cataract would apply. Nine cases were recorded, nearly all of which were complicated with ametropia. In six cases, in which the children were discovered to have disseminated dot cataract, the same condition was found in the mother. In no case in which it was present in the child was it absent in the parent. In two cases it was present in the parent—once the father, once the mother,—but absent in the offspring.—Mr. SYDNEY STEPHENSON said he had seen a number of cases like those described by Mr. Wray, and in several he had noted congenital defects of the eyes—for example, opaque nerve fibres, persistent pupillary membrane, &c. He asked if Mr. Wray had found such defects in his cases.—Mr. LANG said that, in his experience, the lens was easily extracted in cases of dotted cataract with nearly clear cortex, and he had consequently no hesitation in advising operation.—Mr. LAWFORD thought the vacuoles in the lenses alluded to by Mr. Wray were not uncommon in cases in which no other evidence of lenticular change was forthcoming. He had observed some

Digitized by Google

cases for three or four years, and had been unable to detect any increase in size or number of the vacuoles. He asked whether their presence had any significance.—Mr. DOYNE was unable to agree with Mr. Lang as to the ease with which these dotted cataracts could be extracted. He had found considerable difficulty in removing the cortical portion of the lens.—Mr. GUNN inquired if the dots of opacity were very numerous, and Mr. Juler inquired if the condition was not generally progressive.—Mr. WRAY, in reply, said that the dots in the lens were generally present in large numbers. He thought that the opacities in most cases remained nearly stationary. He had seen one case in which there was a persistent hyaloid artery.

The following cases and card specimens were shown:—

Mr. CRITCHETT: A case of Conical Cornea, treated by Galvano-cautery without Perforation.

Mr. GUNN: Apparatus for Illuminating the Eyeball from behind.

Mr. JULER: Microscopic Demonstration of Hyaloid Growth from the Lamina Vitrea of the Choroid.

Mr. HIGGENS: Tuberculosis of Iris.

Mr. ERNEST CLARKE: Case of Unusual Retinal Detachment (?) Neoplasm.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

THURSDAY, JAN. 14TH.

Mr. W. DALE JAMES, M.R.C.S., in the chair.

Gastric Ulcer.—Dr. GORDON related a case of Gastric Ulcer with Gastro-colic Sinus, and showed the specimen. A young woman came under his treatment for vomiting. She had always been subject to constipation, and three years previously had been attacked with sickness and vomiting, which continued more or less frequently until she came under his notice. Rest in bed and bismuth and soda mixture relieved the sickness completely for six weeks, but it eventually returned without any apparent cause. The vomited matter then became stercoraceous, but on no occasion did any undigested food appear in the motions. The case was then supposed to be one of chronic constipation with the large bowel lined with fæces. Enemata were ordered, but on the fourteenth morning the patient vomited a pint injection of soap-and-water ten minutes after it had been administered. From this time she gradually sank, and died from exhaustion. At the necropsy, only sufficient peritonitis was found to unite the peritoneal surface of the stomach to the transverse colon at the seat of the ulcer, thus preventing the gastric contents from passing into the peritoneal cavity, when perforation took place through the sloughing of the base of the ulcer. The communication between the stomach and colon was circular in shape, three-quarters of an inch in diameter, and situated on the posterior surface of the stomach two inches from the pylorus. There was an absence of lienteric stools throughout the whole progress of the case.

Dr. SOMERVILLE showed four pairs of Lungs presenting the character of Fibroid Tuberculosis, which had been taken from men engaged in "dry grinding." After reading brief clinical notes of the cases, he drew attention to the following points: (1) The pleural thickenings; (2) the tubercles, which were pigmented and of large size, being from one-eighth of an inch to half an inch in diameter, and so closely arranged in some parts as to give the lung a very dense feeling; (3) the cavities which lay between fixed points, and had smooth walls; (4) the bronchial glands; and (5) the microscopic appearances. Dr. Somerville also remarked on the pathology of this form of phthisis.

Treatment of Phthisis.—Dr. HUNT read a paper on the Treatment of Phthisis. He gave his experience of various modes of treatment during the past ten years, which had led him to place little reliance on the use of drugs except for the purpose of relieving distressing symptoms. He pointed out that the only hope of successfully curing phthisis must depend on being able to attack the disease at its seat of origin. This mode of treatment had a sound pathological basis, and all the latest experiments encouraged perseverance in this direction. The results, in a great number of cases treated by antiseptic injections into the lungs through the larynx, were related by Dr. Hunt, who said that the good obtained by residence in high altitudes was due to the antiseptic influence of the atmosphere, and concluded by referring to the successful results obtained in the case of several of his own patients who had been sent to Davos Platz.

THURSDAY, JANUARY 28TH.

Dr. MARTIN in the chair.

Mr. R. FAVELL showed a specimen of Hæmato-salpinx removed from a woman thirty-four years of age. The tube was distended to about the size of a small orange, and was filled with blood-clot. From examination there was apparently no evidence of the tube being gravid. Mr. Bland Sutton had kindly examined the specimen, and his opinion was that it was a case of true hæmato-salpinx.

Malignant Disease of the Mesentery.—Dr. KERR showed specimens from a case of this kind. The patient, a man aged thirty-three, had been under Dr. Dyson's care in the infirmary. There was a seven months' history of abdominal pain, especially towards the left side, aggravated by food, with loss of flesh, and latterly some sickness. The patient had been a hard drinker. On examining the abdomen a tumour was felt in the left hypochondrium, projecting beneath the costal margin and extending into the left lumbar region. The growth was movable, had a rounded end, and could be tilted from behind. There was some tenderness over the tumour, and more still over the umbilical region where the tumour was not felt. The tumour simulated an enlarged spleen. The blood when examined was found normal. The tumour increased very rapidly in size after admission, enlarging towards the epigastrium, and becoming softer, semi-elastic, and very tender. The patient died within two months of admission into the infirmary. Post-mortem examination disclosed a large mass of new growth occupying a great part of the abdomen, especially the left hypochondrium, protruding below the ribs and extending up in front of the spleen, which was small but healthy. The mass was soft and pulpy, nodulated, and firmly adherent to the stomach. The liver was enlarged, and infiltrated with new growth. Microscopically the growth showed alveoli of delicate connective tissue filled with masses of round cells, which were granular and had well-marked nuclei—doubtless encephaloid cancer.

Ulcerative Colitis.—Dr. DYSON read a paper on Ulcerative Colitis. He related a case and showed the colon of the patient, who died in the infirmary while under his care. The patient was a man aged thirty-nine, a traveller. He had been in the Horse Guards, but had never been abroad. There was no history of syphilis, alcoholism, or dysentery. The cause of the disease was not clear. The patient was very sallow, cachectic, and emaciated. He was very severely ill for two months. He suffered from severe and uncontrollable diarrhœa, the motions generally being fluid, ochre-coloured, offensive, and latterly containing blood. There was occasional pyrexia, but the temperature for the most part was normal or subnormal. There was no pus or mucus seen in the motions. The patient died of asthenia. Remedies, consisting principally of opium and astringents, were of no permanent effect. Dr. Dyson referred to the cases reported by Dr. Hale White. The prognosis was almost always bad. Post-mortem examination in Dr. Dyson's case showed severe colitis with ulceration, extending from the middle of the transverse colon to two inches above the rectum. The ulcers were numberless, some well defined, some extending deep down to the peritoneal coat, many of them coalescing, leaving prominent islets of uninvolved mucous membrane between. Dr. Dyson also related a case of follicular ulceration of the colon, laying stress on the great importance of distinguishing between these two varieties of ulceration and also on the importance of not confounding them with severe colonic catarrh with the presence of casts in the motions.

MIDLAND MEDICAL SOCIETY.

WEDNESDAY, NOV. 25TH, 1891.

Mr. BENNETT MAY, F.R.C.S., President, in the chair.

Molluscum Fibrosum.—Dr. SUCKLING showed a woman aged seventy who was covered with fibrous tumours varying in size, some pendulous, some sessile. The growths commenced thirty years ago, and fresh ones had continually appeared since. There was no hereditary history, and no

Digitized by Google

cause for the disease could be elicited. None of the growths had ever disappeared spontaneously. A few of the growths had a comedo on the summit, and there was a large one growing from the mucous membrane of the hard palate. Some of the tumours were lobulated. The disease could be easily distinguished from multiple neuromata, lipomata, and from molluscum contagiosum.

Mr. JORDAN LLOYD showed a patient forty years of age upon whom he had performed the operation of Kolpohysterectomy for uterine cancer in May last. The tumour was epitheliomatous, affected the whole of the cervix, and had existed for six months. The operation was performed in the usual manner, the left broad ligament being clamped and the right one ligatured. Recovery was uninterrupted. She had gained more than a stone in weight, and her skin had become ruddy and firm again since the operation. She was free from pains, and able to do her housework as well as ever. Mr. Jordan Lloyd also showed a large Myxomatous Tumour removed from the right popliteal space of a woman about sixty-five years old. The whole of the structures of the space were spread about the growth, which weighed three pounds after removal, and had been slowly growing for nearly twenty-five years. Of late, however, it had increased with great rapidity. The patient was making a good recovery.

Dr. MALINS showed a Fibro-cystic Tumour of the Uterus. The patient was forty-one years of age; no family or miscarriages. She complained of pain in the left side of the chest. A tumour was found in the right side of the abdomen, thought to be ovarian. It was attached by a pedicle one inch wide to the right side of the uterine fundus; it was filled with about two pints of clear fluid, and its interior was degenerating—i.e., breaking up. The pelvis was washed out with water, a glass drainage-tube being kept in for thirty-six hours. The patient left the hospital quite well on the twenty-fifth day. Dr. Malins also showed a Polypus. The patient was forty-four years of age; two children; married twenty-seven years; history of menorrhagia for four years. The patient was blanched and anæmic, and she had never been examined until just before admission. The polypus was excised on Nov. 17th. The patient has done very well since.

Calculus impacted in Ureter forming Sub-vaginal Tumour.—Mr. JOHN W. TAYLOR narrated two recent cases of calculus impacted in the ureter which he had diagnosed from the presence of a little painful tumour felt on vaginal examination in the situation of one ureter near its entrance into the bladder. In one of the cases the stone had passed, with disappearance of the local tumour. In the other case the tumour persists.

Dr. STACEY WILSON showed a very typical specimen of Pemphigus.—Mr. HALL EDWARDS read a paper on the Optical Lantern as an Instrument of Medical Education. A number of slides of diagrams, cases, micro-photographs, and pathological specimens were exhibited on the screen.

BRADFORD MEDICO-CHIRURGICAL SOCIETY.

TUESDAY, DEC. 15TH, 1891.

J. H. BELL, M.D., in the chair.

Acromegaly.—Mr. APPLEYARD showed a woman aged forty-three, in whom, since twenty, there had been persistent amenorrhœa. The relatives had noticed no particular change in her features or voice. Ten years ago her hands and feet were noted, as increasing in size. Half-a-dozen years ago a curvature forwards of the upper part of the spinal column began to show itself. The voice was deep, forehead retreating, orbital and malar ridges well developed, lower jaw natural size, the bones and areolar tissue of hands and feet uniformly enlarged, the skin soft and thickened. Some years ago she frequently noticed outbursts of sweating in hands and feet, not so evident now. When the hands are extended the metacarpo-phalangeal joints are over-extended, the terminal phalanges being slightly flexed. Both the clavicles and first ribs on each side are considerably enlarged. The mucous membrane of the mouth is more succulent than natural, and the lower lip markedly everted. Reflexes and special senses normal. No alteration of fields of vision, no headache, vomiting, or evidence of intra-cranial tumour, no albuminuria or glycosuria, no signs of tubercle in lungs, but difficulty of respiration; bronchial catarrh, for which she is under treatment; the mental state a little inert; great muscular weakness. When first seen, two months ago, could not walk across a room.

Lupus inert to Tuberculin.—Dr. BELL showed a case of lupus under observation for very many years, which had been treated for twelve months past with tuberculin; improvement had resulted, but the disease was there still, and maximal doses corresponding to one cubic centimetre of undiluted tuberculin now had no effect on either patient or disease.

Sarcoma of Femur.—Mr. APPLEYARD showed a specimen on a case of accident; femur fractured whilst walking in the street. As union did not take place, and callus was suspicious, it was cut down on and found to be a rapidly growing sarcoma.

Other Cases &c.—Dr. S. LODGE: Bilateral Palsy of Laryngeal Abductors, improving under iodides. Mr. WILMOT: Lupus Erythematosus in a Child. Mr. HORROCKS: Chronic Hydrocephalus with Meningocele treated by operation. Mr. PETTITT: Enlarged Dislocated Spleen in Infant. Dr. ADOLPH BRONNER: Cases of Atrophic Rhinitis of fetid and non-fetid nature, and a case of Peculiar Laryngeal Growth. Dr. RABAGLIATI: Sarcoma of Kidney; Nephrectomy. Mr. HORROCKS: Scirrhous Mammæ, with Organised Blood-clot. Mr. APPLEYARD: Peculiar Skin Disease allied to Molluscum Contagiosum.

Reviews and Notices of Books.

A Clinical Text-book of Medical Diagnosis for Physicians and Students. By OSWALD VIERORDT, M.D., Professor of Medicine at the University of Heidelberg. Authorised Translation by FRANCIS H. STUART, A.M., M.D. (New York). Edinburgh and London: Young J. Pentland. 1891.

THE somewhat extensive series of text-books dealing with the methods of physical diagnosis which within the last decade have been placed at the disposal of the English reader has been certainly enriched by the addition of Prof. Oswald Vierordt's work, for the translation of which the profession is indebted to Dr. Stuart. The subject is one which is not capable of great variety in the manner of its presentation, but very much indeed depends upon the author's exposition of it and his appreciation of the relative importance of the facts he describes. It is of great advantage to the learner, moreover, to meet with a writer on the subject whose position as physician and professor enables him to speak from the fulness of personal experience, and who knows also the best method of systematising his material in order that it may be of the greatest service. The methods and instrumental aids to diagnosis have now become so numerous that it is no light task for a physician to describe them fully and satisfactorily; and even in the present volume, which in its exhaustive character equals any that has hitherto appeared, it has been deemed fitting to relegate to an appendix the subjects of laryngoscopy and ophthalmoscopy, the full treatment of which would have necessitated a great increase in the bulk of the work.

The plan on which the book is arranged is that usually adopted in works of this class, for indeed it is the natural method of the systematic treatment of the subject. First, the results of general observation and examination of the patient, his nutrition, the state of the skin and subcutaneous tissues, and the temperature of the body. There is no material point left untouched by the writer in this section, and opportunity is taken now and then of entering more fully than usual into pathological questions; as, for instance, when speaking of jaundice, the suggestion is made that in many cases of so-called hæmatogenous jaundice, associated with hæmoglobinæmia—i.e., destruction of red corpuscles,—the bile may be so thick and concentrated as not to flow through the duct. At the same time, it is not disputed that hæmatoidin (or bilirubin) may be formed from

Digitized by Google

the hæmoglobin set free in the bloodvessels, thus constituting a true blood-jaundice. In describing the precautions needful for the accurate observation of the temperature of the body, Professor Vierordt emphatically recommends that the temperature should not be taken in the mouth; but we are of opinion that when due care is observed to place the bulb of the thermometer beneath the tongue there is not much risk of fallacious results.

The next section deals with the Examination of the Respiratory Apparatus, and contains many valuable hints as to the practice of percussion and auscultation. The interpretation of the results of percussion, according to the physical conditions of the parietes, is assisted by a series of novel and accurate diagrams. The author is no advocate for the use of the binaural stethoscope; and herein we agree with him, at least in part, for we deem it unwise of the student to cultivate the use of this instrument to the exclusion of obtaining familiarity with the rigid stethoscope. Professor Vierordt wisely refrains from any detailed discussion upon the causation of the vesicular murmur, and contents himself with expressing his belief that "vesicular breathing" is merely the bronchial breath sound formed at the rima glottidis and altered by being prolonged into the air-containing lung. It certainly conduces to clearness to start with the conception of vesicular and bronchial breathing as the root sounds (if we may so express it) of all the variations in the respiratory murmur that appear in various conditions of disease. We confess to a slight disappointment in finding that one so versed in auscultation and its meaning should have retained the word "râle" to comprise the "dry" rhonchal as well as the "moist" crepitant adventitious sounds. To be sure there is high authority for this, but the misuse of the terms is liable to be confusing to the tyro. There is an ample discussion upon the characters of expectoration and its microscopical investigation.

In the following section, that of the Examination of the Circulatory Apparatus, the reader will find a clear and sensible description of cardiac signs and murmurs, and an adequate description of the pulse and of the changes met with in the blood. It will be seen, too, that the author holds that the murmur distinctive of mitral stenosis is diastolic or presystolic, as tested by the carotid pulse; but we find no mention of visibility of the auricular impulse in this affection (page 203). He points out that systolic retraction, limited to the apex beat, is of no significance, whereas a similar phenomenon visible over several interspaces is distinctive of adherent pericardium. Respecting the area of cardiac dulness and the variations assigned to it, he wisely recalls the fact that the precise limits vary with the individual observer. He does not attempt to explain the causation of anæmic murmurs.

The section dealing with the Digestive System necessarily contains an account of the various plans, none of which have gained much footing in this country, of the examination of the gastric secretion, both as to its capability of digesting food and of its relative contents in hydrochloric and lactic acids. The inadequacy of many of the tests devised for this purpose is pointed out. The details of examination of the various abdominal organs and the investigation of the excreta are well and amply discussed. The same may be said of the section devoted to the examination of the Kidneys and the Urine, although we miss any reference to the remarkable reaction discovered by Ehrlich in certain febrile states. But perhaps the most fully developed section is that which deals with the Nervous System, and we commend this for careful study as being a valuabe systematic exposition of a difficult subject. It is thorough and exact, reflecting great credit on the author, who indeed has rendered no mean service to medicine in having prepared a work which will prove as useful to the teacher as to the student and practitioner. The translation is on the whole excellent; now and then the reader meets with novel phrases and crudities of expression, and there is an occasional lapse in the spelling of proper names, as "Veil" for Weil (pp. 103 and 108), "Scoda" for Skoda (p. 109), "Gabett" for Gabbett (p. 187), "Bamber" for Bamberger (p. 190), "Neiser" for Neisser (p. 427), and "Gmellin" for Gmelin (p. 492), but these are only venial faults, and are well atoned for by the general excellence of the work, its admirable index, and elegant production.

A Manual of Practical Hygiene. By the late EDMUND A. PARKES, M.D., F.R.S., Professor of Military Hygiene in the Army Medical School. Edited by J. LANE NOTTER, M.A., M.D., F.C.S., Professor of Military Hygiene at the Army Medical School, Netley. Eighth Edition. London: J. & A. Churchill. 1891.

FROM the time that the late Professor Parkes first published his manual of Practical Hygiene up to the present day it has occupied the foremost position among works of the kind. It was what may be termed an epoch-making book, and its intrinsic merits were at once recognised. After Dr. Parkes' death in 1876, the late Professor De Chaumont continued to edit the new editions called for from time to time, and now the eighth edition has been brought out by the present Professor of Hygiene at the Army Medical School, Dr. J. Lane Notter. In the case of a book of 769 pages, and supplied with copious references and foot-notes, it would be impossible within reasonable limits to afford anything like an adequate idea of its scope, method of treatment, and the alterations and additions that have been made since the publication of the last edition. And, happily, it is unnecessary; for when a work has attained the popularity of "Parkes' Hygiene," little, if anything, remains to be said about it by the reviewer. Its success speaks for it. The book has been a more fruitful source of good to the soldier and the State than can be easily realised. It is full of instruction for the medical officer and, indeed, for all who have anything to do with questions of hygiene and public health. Professor Notter tells us in his preface that when Dr. de Chaumont died, in 1888, he left nothing to indicate that he contemplated any change in the general plan of the manual, consequently the same arrangement has been adhered to in the present edition. While the scope of the work remains unchanged, however, every chapter has undergone careful revision, and as far as possible been brought up to date. Indeed, there is scarcely a page in which additions or alterations do not occur. A comparison of the present with former editions, so far as we have made it, shows this to be the case. To name a very few, we may say that in Chapter I., on Soils, we trace numerous alterations and additions, especially in connexion with soil influences and temperature on disease, soils in order of healthiness, and micro-organisms in soil. There is a fresh section on the Bacteriological Examination of Water, and an important addition on Field Organisation in War. The manual is furnished with a good index.

Professor Notter thanks Mrs. Bruce for the drawings illustrating the characters of starches and bacteria, and expresses his sense of indebtedness to his friend and colleague Surgeon-Captain A. M. Davies, Assistant Professor of Military Hygiene, for his revising aid. The editing of a book of this kind involves great research and the exercise of thoughtful care and of a cultured judgment, and the eighth edition of Parkes' Practical Hygiene reflects much credit on the Army Medical School.

New Inventions.

SHOT-PROOF SPECTACLES.

THE constant recurrence of serious accidents to the eyes of gunners and others engaged in covert and various kinds of game shooting has induced Mr. Steward of the Strand to direct his attention to the manufacture of a pair of "shot-proof spectacles" which should protect the eyes of its wearer. The danger is now sadly increased by the employment of new pattern of spectacles, and it was clearly shown by demonstration, after firing Nos. 5 and 6 shot at different ranges, that down to forty yards the lenses, manufactured from stout pebble or Brazilian quartz, were "*shot-proof.*" The pellets did not in any instance penetrate the lenses, although in some cases they cracked them, whereas with glass lenses of the same thickness the glass was shivered to pieces. The spectacles weigh about one ounce, or one-third the weight of the regular commercial *D* eye shot-proof spectacles. The shape when finished is a well-domed oval, so as to fully protect the eyes in front and at the sides, and the

"chilled shot," which, hardened as it is, does not flatten and fall as soft shot does, but glances off in every conceivable direction after striking any hard substance. The spectacles are made to fit the eyes most accurately, and can be worn without inconvenience. Captain Willoughby Verner, of the Rifle Brigade, has recently carried out some experiments fully proving the protective power to the eyes of this *front* of the frame is bowed so as to preserve the proper curve. The thickness decided on is much less than in those previously introduced, and has been arrived at after several experiments to determine a reasonable minimum of substance for safety. With the sighted lenses the thinnest part is of equal thickness to the weakest part of the lenses used at trial.

THE "EUCALYPT" AUTOMATIC VAPORISER.

IT is well known that the treatment of disease by inhalation has been employed with marked benefit, but it must be admitted that the methods that have been previously adopted are not so perfect as to call for no further improvement. The "eucalypt" automatic vaporiser seems to us to fulfil two very desirable conditions which do not appear to have hitherto attracted notice—namely, that the supply of medicated vapour should be independent of any effort of the patient, and that the supply should be continuous over long periods of time. The illustration will serve to show how these ends are attained. The vaporiser consists of two upright metal bars, about two feet high, fixed opposite to one another on a firm circular wooden base, which, uniting at the top, terminate in a ring, so that the whole apparatus may be lifted and moved from one place to another. A special form of night-light rests in a socket in the centre of the base, and is covered with a glass shade. A metal pan containing a porcelain evaporating basin is suspended over the light by means of guides which slide freely up and down the upright bars. The guides are furnished with spring catches fitting into numbered notches cut into the bars, in order that the water bath with its evaporating basin may not only be brought near to or raised away from the source of heat, but may be fixed at any desired height. A thermometer is fixed in a support, which slides along one of the upright bars above the pans. The liquid to be vaporised is placed in the porcelain evaporating basin, which is immersed in water contained in the metal pan. Heat being supplied to the metal pan from the night-light, the water becomes heated and the liquid is gently vaporised. The amount of heat supplied and, therefore, of vapour given off is regulated by the height of the water bath above the night-light—the lower the water bath the greater the supply of heat, the amount diminishing progressively as the water bath is raised away from the source of heat. By means of the thermometer, which, when in use, is lowered until its bulb is covered by the liquid in the evaporating basin, the temperature at which the evaporation is going on can be at all times observed.

We find that the action of the vaporiser can be regulated with the utmost ease, and when once it is set it requires no more attention than an ordinary night-light, at the same time securing the steady diffusion of antiseptic vapours into the atmosphere. The apparatus may also be used for the vaporisation of other substances, such as thymol, lavender, terebene, phenol, iodine, and iodoform. It is the design of *Dr.* W. H. Spencer of Hastings, and is made by Coxeter and Son, of Grafton-street, Gower-street, W.C.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 6, 1892.

IT does not appear to be probable that the judicial decision in the recent action STEELE *v.* SAVORY will affect detrimentally the ultimate settlement of the constitutional questions still awaiting solution at the Royal College of Surgeons of England. The decision may merely mean that the plaintiffs in this action proceeded upon too technical legal advice when they deliberately infringed the by-laws of the College and set at naught the authority of the Council for the purpose of testing the validity of claims which had been raised on behalf of the Members. As the matter now stands, the result of accepting the advice tendered to the plaintiffs in the action STEELE *v.* SAVORY is that the adverse decision of Mr. Justice ROMER leaves them exposed to the infliction of the penalties set forth in the broken by-law, in addition to the payment of the costs of the action. We do not for a moment believe that the Council of the College will think it advisable to act upon the powers which they possess. The plaintiffs have been judicially declared to have been in the wrong; and not a few of those who ardently desired a reform in the College have throughout disapproved of the tactics which the Association of Members adopted. Nevertheless, we cannot withhold sympathy and best wishes for the ultimate attainment of the end in view—namely, that of improving the constitutional position of the neglected Members of the Royal College of Surgeons of England.

It is rumoured that the plaintiffs intend to appeal against Mr. Justice ROMER'S decision. We cannot but conclude that an appeal would serve only to keep up an irritating cause of difference which it is desirable in the interests of both of the Fellows and Members of the College to remove as quickly as possible. It would delay the reforms which are now accessible without benefiting in the smallest degree either the plaintiffs or the Members of the College. Even if it were proved that the Charter of 1800 had been irregularly secured, it would not be possible to go back to the conditions established by the Act of 1745. The cause of reform would not be advanced unless the whole fabric of the Charters and by-laws commencing in 1800 could be swept away and a *tabula rasa* obtained. Then perhaps the claims of the Members of the College to a substantial voice in the management of the corporation might receive due recognition.

If we set aside the hope of assistance from the judicature, there are only two ways in which the desired reforms can be secured—viz., the action of Parliament and the moral suasion which results from strong arguments founded on justice and expediency. At the present time it would be idle to expect any redress from the Legislature. When a new Parliament has been elected and gives promise of stability, it will be time enough to estimate the prospect of relief from legislation. The only course which remains is a temperate representation of grievances and inequalities to the governing body, the enlistment of the sympathies of a majority at least of the Fellows of the College, the electoral body to the Council, and the conversion of the members of the Council of the College. Future success must depend upon the strength of the forces which the Members of the College can bring to bear upon the Council. An association of Members of the College aiming to realise the just aspirations of the Members to a substantial voice in the management of the corporation ought to include every Member who thinks for himself and aspires to something more than securing for himself and his family the bare means of subsistence; the Members of the College must show that they are a united body, and are really in earnest in vindicating their claims; it is by such means as this that they must convince the Council of the College of the justice and the expediency of yielding to them some representation on the Council of the College.

The profession at large fails to take its proper place in the estimation of the public and the Government of the country, because it lacks, and has ever conspicuously lacked, that *esprit de corps* which is the first element in the elevation and success of bodies of men associated for a common purpose. The leaders of the profession have seldom been on the side of the rank and file in their efforts to obtain increased consideration in the corporations or institutions concerned with professional interests. The stocks, the loss of ears, the fines and imprisonment which formerly were at the command of the College of Physicians in dealing with offenders against its laws more nearly represent the spirit in which the upper crust of the profession has regarded the aspirations and ambition of the lower layers. There are no very obvious signs of any abatement of an antagonism which seems to be innate. Professional brotherhood is too often limited to consultations and social gatherings. At other seasons each class fights for its own hand. The forces of the Members of the College, being large and scattered, are not readily mobilised; but if they wish to lift the cart out of the rut in which it is embedded, they must avoid calling upon JUPITER, and put their own shoulders to the wheel. No better or surer way can be suggested than by making the Association of Members of the College so strong that its voice will be recognised as the true expression of professional feeling and opinion.

WHATEVER significance may be attached to the term "masked epilepsy" from a pathological point of view, it is devoutly to be hoped that it is not to be frequently called upon to do duty in criminal cases, either as a shelter from responsibility or as a refuge from punishment. The case of EDMUND OSBORNE, an elderly and delicate-looking man, who was tried before Mr. Justice CAVE at the Central Criminal Court on Jan. 13th, affords an admirable illustration of the incongruity of opposing evidences and opinions as to the presence of a "disease" whose chief characteristic is its obscurity. According to the account of the trial given in the *Daily Telegraph* of the following date, OSBORNE

Digitized by Google

was placed in the dock on a charge of maliciously wounding his wife with intent to murder her, the allegation being that on Nov. 10th he returned home in a state of intoxication and savagely assaulted the prosecutrix with a poker, inflicting serious wounds. Believing that he had killed the unhappy woman, OSBORNE went to his daughter and announced his intention of giving himself in charge. The contention on the part of the defence was that at the time of the attack the accused was irresponsible for his actions. It was asserted that there was insanity in the prisoner's family, some of whom had suffered from epilepsy, and that it was while under the influence of that malady in its "masked" form that the accused committed the assault. Mr. GROGONO, divisional surgeon of West Ham, explained that victims of this disease betrayed none of the symptoms of ordinary epilepsy, and that a man suffering therefrom would fall down insensible. His Lordship: But so would a drunken man.—Witness: Yes, but you could waken a drunken man, and for your good nature he would probably swear at you, whereas in the other case t would be very difficult to bring him round. In reply to the counsel for the prosecution (Mr. F. FULTON), witness admitted that the diagnosis of the complaint was somewhat obscure. Mr. PITCAIRN, assistant surgeon of Holloway Prison, was of opinion that the accused was perfectly sane on the night in question, and in reply to Mr. MATHEWS, who defended, he remarked that the disease spoken of was usually advanced in criminal cases, and was held in doubt by high medical authorities. Mr. F. FULTON subsequently admitted that he had never heard of such a form of mania as the one in question; but Mr. MATHEWS was very emphatic on the point, and his description (says the *Daily Telegraph*) was calculated to throw terror into the minds of peaceably disposed citizens. "Years and years," he declared, "it may lie dormant in the brain; but if once it shall show itself it will take the form of ungovernable temper, resulting either in suicide or homicide."

The learned judge, in summing up the case, said, so far as he could gather, "masked" epilepsy masqueraded in the form of drunkenness, and the question therefore arose, "How was one to tell these two things apart?" The jury, however, experienced apparently no difficulty of this kind, and found the prisoner guilty, adding that they believed him to have been under the influence of drink at the time, and some of the jurors recommended him to mercy on the ground that "he was a man of excitable temperament." Mr. Justice CAVE, observing that the case came uncommonly near murder, passed sentence of eighteen years' penal servitude. We can well imagine that EDMUND OSBORNE, on hearing his sentence—no light one assuredly—felt disposed to wish that he had been "saved from his friends." It is clear that upon the evidence the jury had no choice but to hold OSBORNE responsible for the criminal act which he had committed.

When irresponsibility is urged in defence of a prisoner and as a plea against punishment for a crime, it ought to be put forward only upon positive evidence of the existence in the accused person himself of such a condition of mind as would render him irresponsible, and not upon flimsy generalities that scarcely leave room for such a thing as crime in human action. Leaving out the question of persons who are habitually criminal-minded, it may in general terms be taken that no civilised man is, mentally speaking, at his healthiest while engaged in committing a crime; there is at the time a special disturbance of his normal mental balance, by exaggeration or defection of one or more of the processes or faculties whose proportionate distribution and operation constitute his mind in its healthy state. Yet such deviation from the individual's normal best is not to be taken as implying disease or irresponsibility, otherwise all social rule and discipline must be set at naught, and give way to the incoherent sanctions of savagery. On the other hand, insanity, whether in company with epilepsy or not, is properly regarded as a disease, carrying with it irresponsibility and demanding special consideration and treatment. But it would be deplorable if this diseased condition, which carries with it irresponsibility, were to be minimised down to such proportions as are indicated in the phrases "ungovernable temper," "excitable temperament," and "masked epilepsy."

The learned judge's belief that in EDMUND OSBORNE masked epilepsy masqueraded in the form of drunkenness, appears to sum up the situation accurately and concisely, and we hope the day is far distant when in criminal cases mere drunkenness will be regarded as a disease, and not as in itself a crime antecedent to the one up to which it was the means of leading.

THE meeting of Parliament and the consequent demand on the columns of our contemporaries will probably tend much to diminish the number of specifics for influenza vaunted in our daily newspapers. At present the number and variety of these are embarrassing. The lay mind must be puzzled what course to take most effectually to foil the malicious microbe that has caused such ubiquitous mischief throughout this country, and, indeed, throughout almost all countries. One morning all that is necessary, either for the prevention or cure of the disease, is a sniff of an aromatic oil; another day the anxious public is assured that a few doses of a sweating mixture, without discrimination of cases, will divest the attack of all its dangers, and meet all its symptoms. Magazine articles are published disclosing not only the author's name, but the way in which he protects himself, and cures all his patients so effectually that they rarely give him any anxiety. A reader cannot but wonder that with such simple theories of the disease an such effective remedies there should be all this amount of sickness, and a demand for medical services seldom, if ever, equalled in this generation. In trying to form and express a judgment on the treatment of influenza we have to confess at the outset that we have no such brilliant successes to announce, and no single remedy to vaunt as meeting every case and every symptom of every case. There is no disease in which it is so easy to satisfy oneself of the efficacy of a pet remedy and the truth of a plausible theory as in the case of influenza. It will be our endeavour to indicate the general management of the disease, based not on the supposition of the existence of a specific cure but on its general nature, the character of its chief symptoms, and its usual course.

It seems not improbable that men in speaking of influenza in the lump are speaking of very different things. One

Digitized by Google

thing is certain: that the chief mortality which has been witnessed lately, and which has so shocked the public mind, is not the mortality of mere influenza, but of pneumonia, bronchitis, and pleurisy, single or combined. The special character of such pneumonia, bronchitis, and pleurisy is to be inferred from the extensive prevalence of influenza, from the nature of the initiatory symptoms in many such cases, and from the fact that in the same house in which a patient has suffered, and perhaps died, from such complications, others have had ordinary attacks of influenza with little or no complication, and with quick recovery. For the most part such complications have been witnessed in older persons, and the proportion of such cases has been larger in the present outbreak than in the previous ones.

Nothing can be more misleading than for scientific men to write, especially in lay journals, as if all cases of influenza were alike, or as if a remedy that would appear to advantage in short febrile cases of the disease would be equally efficacious in pneumonia. Few cases are more easily managed than the run of influenza cases, especially in young subjects. Rest in bed, light diet, and a draught of citrate of ammonia and syrup will in nine cases out of ten secure the fall of the patient's temperature to normal in twenty-four, or at most in forty-eight, hours. He is likely to be so well as to wish to be up and about. In this he will be hindered by a wise practitioner, who has learnt that mere rest in bed for a few days, varying according to the case and the constitution of the patient, is the surest way of preventing future trouble, of averting sequelæ or relapses, and of securing restoration from that strange nervous and muscular asthenia which constitutes such a marked feature of the disease, and which in so many cases prolongs the convalescence for days or weeks, or even in some cases for months. In most cases the early use of quinine is beneficial. If a tendency to an evening rise of temperature continues, with profuse nocturnal perspirations, a four-grain dose of quinine at 4 P.M., or night and morning, has a steadying effect on the temperature and the sweat glands. The course of the disease is infinitely varied. One patient will have a very foul tongue with absolute anorexia and loss of all taste and smell, for which, with or without the quinine, light laxatives, such as a seidlitz powder or small doses of blue pill and rhubarb pill, are indicated. In other cases the pains are very pronounced in the head, back, or body. They are differently, but very vividly, described. The head and eyes are as if being crushed, the back as if being broken; in the limbs it is as if the flesh were being torn from the bones. Such pains often persist when the temperature has fallen. It is in such cases that antipyrin often seems to act like a charm, and, indeed, rarely fails to give relief in ten or fifteen-grain doses, once or twice repeated. Quinine, antipyrin, salicin, and many other drugs are useful in this disease. But the selection of them should be discriminating according to the idiosyncrasy of the sufferer and the physician's knowledge of the patient and his diathesis. In some cases there is very marked anæmia, and faintness with vertigo on the slightest attempt to sit up or move about, calling for the regular administration of nourishment and stimulants, and a very firm resistance to all premature attempts to resume the erect posture. All physicians must have noticed the severe reverse, almost shock, which many patients experience who have got up too soon or sat too long on the first day or two of their escape from bed. In a considerable number of cases the administration of alcohol very materially helps the patient and shortens his convalescence; and where it is practicable and otherwise unobjectionable, champagne is the form of alcohol which seems most useful. Of course in this, as in all other diseases, the prescription of alcohol is to be regarded seriously, and the physician is to prescribe it under strict conditions of time and dose. But with such limitations its usefulness cannot be ignored.

If the evening temperature in a case of influenza continues to rise after forty-eight hours, some complication is probably present, and it will generally be found in the bronchial tract or in the tonsillar or pharyngeal region. Here evening doses of quinine will be very beneficial, or salicylates, especially in rheumatic subjects, combined, if necessary, with ammonia and other remedies for the relief of the bronchial catarrh, and other local or topical applications. We are not now dealing with those grave cases of pneumonia which have constituted such a deadly feature of this epidemic, and which are so different in their result from sthenic pneumonia in ordinary seasons. It is, indeed, a question whether these should not be regarded as something apart from ordinary influenza, and more of the nature of the epidemic pneumonia in Middlesbrough and other places investigated so ably by Dr. BALLARD two years ago. We should like to see this point definitely investigated.

One of the most disappointing things about influenza is the prolongation of the convalescent stage. The patient continues weak, or short-breathed, or anæmic, or suffers from pains and soreness of the limbs. In many cases such sequelæ are due to treating the disease too lightly in the first instance, to an insufficient period of rest and recumbency, or an inadequate use of tonics proper to the diathesis of the patient, or else to neglect of seeking change of air; for here, as everywhere else, it is the patient, and not the mere disease, that has to be treated. All patients cannot be treated with one remedy or in one way; they "need a physician"—in other words, one who will go into the particulars of their case, and select from half a dozen remedies the one which they require. But here, again, the medicine or drug is only a small part of the treatment necessary to remove symptoms so deep-rooted and persistent. It is by discriminating treatment, and not by the wholesale prescription of any nostrum, that the welfare of patients and the reputation of the profession are to be secured.

THE more recent telegraphic despatches which have been made public concerning the proceedings of the International Sanitary Conference at Venice have been difficult to understand, and have seemed to indicate some considerable vacillation in the attitude of the British delegates, who, as announced, have been in frequent communication with the Government on the subjects under discussion. As will be remembered they went out to uphold the principles of the Anglo-Austrian protocol, which demanded the passage "in

Digitized by Google

quarantine" of the Suez Canal for all British vessels regarded as "suspect" or infected, provided these did not communicate with land until arrival at their port of destination; and the same privilege was to be accorded to any other nation which desired to make arrangements accordingly. This protocol had the appearance of having been very deliberately prepared by our Foreign Office, which department selected the delegates who were to represent the interests of this country, and it was generally understood that its terms met with favour on the part of the Italian Government. The French counter proposals now appeared on the scene; and without any explanation that could be regarded as reasonable, unless a mere counting of votes be so regarded, it was announced that these proposals had superseded the English ones, and had, with certain modifications, been assented to by our delegates. The two sets of proposals differed in the most important of all the conditions laid down. The one demanded the passage of the canal for all our troopships, mailboats, &c., even if infected, provided they sailed direct to a British port; the other not only refused this passage, but in certain cases demanded an old-fashioned quarantine, by requiring the disembarkation and detention of all the passengers &c. at the Wells of Moses in the case of infected vessels. Then came adjournments, during which the public were informed that the British delegates were in communication with the Home Government; and this was followed by an urgent telegraphic despatch to the chairman of the Peninsular and Oriental Shipping Company to join the delegates at Venice, but before his arrival these arrangements, which had apparently been agreed upon, were again modified, and some of the French proposals were practically set aside.

Then towards the final stage of the proceedings came a further telegram, to the effect that the proposals which England had laid down "regarding the passage of the Suez Canal in quarantine" had been adopted with certain amendments and assented to by the Conference. There still remained such reservations that the British delegates declined to sign the convention which had been prepared until they had received authority so to do from Her Majesty's Government. And this refusal is the more significant, because the latest telegram as yet received states that amongst other things adopted by the Conference is "the detention at Moses' Wells of all infected vessels—that is to say, of those which actually have on board cases of cholera or have had them some days previously." It is true that this is further limited by a reference to the disembarkation of the sick only; but, on the other hand, the same regulation definitely refers to a detention which, as regards the ship—not the passengers—will, in any event, not exceed five days. The arrangements thus provisionally proposed or entered into seem most perplexing, and it will be impossible to form a proper judgment upon them until the actual terms of the Convention have been made public. If Great Britain has seen fit to sanction an alteration in the constitution of the Alexandria Board, by which it acquires an international character, and if our troopships and other ships are to disembark "the sick" at Moses' Wells, it is earnestly to be hoped that the officials who will have the power of deciding who is to disembark shall be such as this country will have confidence in, and that no such measures shall even be commenced until we know that adequate provision has been made for the care of those who are detained.

THE general meeting of the Council of the Hospital Sunday Fund, which was held on Monday last, had a long list of distinguished names to record with obituary references, the deaths of Sir J. RISDON BENNETT, Cardinal MANNING, and Mr. SPURGEON having followed one another in very rapid succession, and it was with very sincere feeling that the Council testified to its sense of the great services which these men had rendered to the common cause. The resignation of Sir RUTHERFORD ALCOCK was also announced. But the chief business of the meeting had reference to the form of hospital accounts which has been elaborated by a committee of hospital secretaries, and provisionally approved by the Council of the Fund for adoption by the various hospitals in rendering their accounts to the Distribution Committee of the Fund. The prevailing feeling at the meeting of the Council was that, for the sake of obtaining uniformity it was worth while to make a beginning with a form of accounts, even though it should have to be hereafter modified, so great is the inconvenience felt by the officers of the Council in dealing with the various forms which are at present received from the hospitals of the metropolis. The need of fuller consideration and the possibility of consequent revision before the schedule can take a final shape were clearly recognised, and this without the slightest disparagement of the painstaking and prolonged work of the committee of hospital secretaries, which has elaborated the present form. That committee has held numerous sittings, and has continued its labours through many months, at what must have been to its members a considerable sacrifice of time and trouble, for which no acknowledgment beyond the thanks of the Council has been or could be offered to its members. It has brought to bear upon the task a large amount of very special knowledge, and the result will command and will receive in all subsequent discussion the most careful consideration, and upon many points will doubtless be accepted as authoritative. The only reason that the work cannot be at once accepted as final is that there are matters to be taken into account which the secretaries' committee did not and could not include in its discussions. The hospital view of the aim and function of the published accounts is a very important one, and the only one which the secretaries' committee could be expected to take of its subject. But it is not the only possible view. When a communication passes between two parties there are naturally two views of it—the view of him who makes and the view of him who receives the communication. In the matter of annual statements, which are communications between the hospitals and the public, we find embodied the views of the one party, ascertained and expressed by what we have every reason to believe is a very efficient representative committee. But no one approaching the subject from the point of view of the public has as yet been consulted by the Council of the Fund; and our own examination satisfies us that when this

Digitized by Google

is done it will turn out, as one would naturally expect, that there are things to be considered in the determination of the schedule which do not naturally suggest themselves to the official mind. The officers desire to speak and the public desire to hear one and the same thing in substance, but in its presentation these are chiefly concerned with difficulties of expression and those with difficulties of apprehension. Both therefore can contribute matter of substance to the discussion, and we reserve a final approval of the form until all available information on the subject has been garnered and thrashed out.

This view of the matter has acquired a special importance at the present time from the circumstance that the House of Lords Committee upon Metropolitan Hospitals has taken evidence upon this subject, and will doubtless deal with it among other matters in the forthcoming report. To any such utterances great consideration will of course be given, and if various forms of statement should come in the end to be competing for recognition, it might well happen that the last state of confusion would be worse than the first. It is plain that the hospitals cannot be asked to serve up one set of accounts to one authority and another set to another authority. Eventually, it is to be hoped that a schedule will be devised that will satisfy all the exigencies of the case and command common consent. The need of uniformity is now pretty generally recognised, and it ought not to prove an impracticable undertaking to devise the schedule which will be on the one hand comprehensive and elastic enough to suit all the hospitals, and on the other hand sufficiently perspicuous and precise to convey full and intelligible information to the ordinary reader.

Annotations.

"Ne quid nimis."

THE ALBERT UNIVERSITY.

DURING the past week an important event has happened with regard to the proposed Teaching University in London. As a result of some negotiations between the authorities of King's and University Colleges and the Joint Grand Gresham Committee, the latter body has unanimously resolved: "That this committee are willing to coöperate with University and King's Colleges and the medical colleges of the great hospitals in London in the establishment of the proposed University in and for London on the understanding that it be called the Gresham University." This proposal will doubtless be adopted by the Councils of King's and University Colleges, and we anticipate that no objections will be raised by the medical colleges, whose delegates will also meet the representatives of the teaching colleges this week, so that a combined action may be taken with regard to the passing of the Charter through Parliament. A mere change in the name, although this is a decided improvement, is the least of the advantages that will be derived if the offer of the Gresham Committee be accepted. The name of Sir Thomas Gresham is pre-eminent in the history of the University movements in London; for as long as some 300 years back he devoted his wealth to founding Gresham College as a Teaching University in and for London. This College will now become such a University, and the numerous bodies represented in the scheme of the University will have a common centre and a home for the meetings of the constituent members. On the other hand, the City will have a University in its midst, where, indeed, a University in and for London should be, and the reproach to this metropolis, that with the exception of Constantinople it is the only capital in Europe without a Teaching University, will be removed by Gresham College becoming the headquarters of the proposed University. It is believed that the change of name can be made before the Charter is submitted to Parliament, as it will doubtless have the consent of all the constituent Colleges, and as the Privy Council intimated in their final decision that the name was open to reconsideration. No other change, we understand, is contemplated in the Charter.

OFFICIAL INQUIRY INTO INFLUENZA.

FOR some weeks past it has been evident that a demand exists both on the part of the public and of the medical profession that further investigation should be made into the subject of epidemic influenza. The report issued by Dr. Parsons last year was admirably summarised in an introduction from Dr. Buchanan's pen; but whilst it settled the question of the infectious character of the disease and of its communicability from person to person, and thus carried with it, by implication, the need for the adoption of the ordinary precautions against a disease spread by such means, it was in many other respects an avowed confession of the lack of knowledge and a plea for further inquiry. "For the better means of repressing influenza," wrote Dr. Buchanan, "our expectation must be in an understanding of the natural history of the disease." Some eight months have elapsed since those words were written; the disease has recurred, and this in a very fatal form; but it has evidently needed the influence of outside public opinion to secure the continuance of the inquiry which was officially proposed. The delay is clearly not due to any lack of desire on the part of the Local Government Board to perform the duty devolving upon it in the matter; but the grant for scientific research allotted to the Medical Department is notoriously determined on a scale which is mainly characterised by rigid economy, and no special work of the sort needed can ever be contemplated except as the result of a special grant. This has at last been forthcoming, and it is to be hoped that it has not come too late to be of real service. The funds thus tardily entrusted to the Medical Officer of the Board will be, in the first instance, devoted to a study of the clinical features of influenza, to investigations as to its special pathology, if any, and to bacteriological research. These are the right lines; and, fortunately, a number of experts accustomed to the more scientific portion of the work are already available, and have already done good work, under Dr. Klein, in investigations of a somewhat similar character, as regards the relation of scarlet fever and diphtheria in the human subject to disease in the lower animals. From the more general and clinical portions of the inquiry we may expect information which will assist in ensuring a differential diagnosis of the disease, in obtaining some more accurate knowledge as to its period of incubation, and a better insight into its pathology. On such information only can any trustworthy means of prevention be based. As regards the present aspect of the epidemic, it is rather to prophylactics, if any exist, and to remedial measures, that we must look; but this subject comes more within the province of such a body as the Royal College of Physicians than of a department dealing solely with public health considerations.

LIFE-SAVING AROUND THE COASTS.

NO part of our telegraphic system now in existence could exceed in utility that which would be added to its range of usefulness if electrical connexion were established with the coastguard and life service depôts distributed around our coasts. When we reflect upon the certain benefit which a project of this kind, if successful, must confer upon us as a maritime people, it seems at first sight incredible that up till the present date almost nothing has been done towards its execution. This neglect, short-sighted and discreditable though it is in more ways than one, is after all not wholly out of keeping with our national conditions. With us, untroubled by disputed frontier questions, the value of a method of communication is apt to be at first, and perhaps for a long time afterwards, judged of by its social convenience and its influence on business only, and the telegraph has accordingly been but little considered in relation either to coast defence or the dangers of coast navigation. It will now, however, be readily conceded that the claims of society and our daily occupations have in regard to this matter been duly allowed for. It is time, and high time, that some practical attention should be given to other and even greater, if not equally constant, necessities. The history of the recent winter storms will recall several sad instances of shipwreck with loss of lives which might and probably would have been saved had a wire been available to summon the earlier services of the lifeboats. A similar argument, of course, holds good in the event of a descent by hostile ships upon our coasts. It is estimated that £100,000 would defray the cost of putting all coastguard stations in night and day wire connexion with the general system, and a series of letters dealing with the whole question have been submitted by Mr. F. H. Maberly, late assistant surveyor, General Post Office, to the Queen, the various Chambers of Commerce, and the members of both Houses of Parliament. The scheme has already been widely approved, and we cannot doubt will at no distant time find that issue in practical reforms to which it is entitled by its great and obvious importance.

TYPHUS FEVER IN LONDON.

MR. SHIRLEY MURPHY, the medical officer of health to the London County Council, has issued a valuable report upon the prevalence in London of typhus fever, which shows to how great an extent this disease, once so common, has been disappearing from the metropolis, thanks, no doubt, in great measure to improved sanitation and the greater vigilance of the authorities. Nevertheless, this diminution of a total of 92 deaths in 1881 to 11 in 1890 must not be allowed to lull us into a false sense of security, although the sparsity of outbreaks and the masked features of some cases may lead to certain sporadic instances being overlooked. This is well illustrated by the record given by Mr. Murphy of an outbreak of the disease in a narrow, ill-ventilated court in St. Olave's, called Sards'-rents, to which his attention was called in October of that year by Dr. Wightwick, the medical officer of health for that district. The inhabitants were of the poorest class, and were occupied chiefly in pulling out of hair from skins. Since January, 1890, there had prevailed amongst them a disease characterised by pneumonic symptoms and delirium. One patient had been removed in March to a public institution and had died there, the death being registered as due to pneumonia. Another had been removed to a general hospital in August, and died from "bronchitis and emphysema." When Mr. Murphy first inspected the court he saw only some children who were recovering; but a few days later other persons sickened, and a careful examination of these cases along with Dr. Wightwick led to the conclusion that the disease was not pneumonia. Although no cutaneous eruption was present, they were forced to the suspicion of typhus fever, an impression confirmed by a study of the recorded history of the hospital case. Therefore, all cases subsequently arising were removed as soon as they occurred, and the suspicion of typhus fever was confirmed by their clinical course. It is satisfactory to learn that some of the houses in Sards'-rents have been demolished under Torrens' Act. Dr. Wightwick estimated that from thirty to fifty persons had been attacked in all, and in November and December eight cases occurred in another street, the outbreak there being doubtless imported by a relative of one of the Sards'-rents people who had nursed them during their illness. The introduction of the Notification Act led to thirty-five cases being certified in thirty districts of the metropolis in the year 1890; but of these only fifteen can be regarded as indubitably typhus, to which number five must be added which are returned as enteric fever. One case occurred in Bermondsey, in the same street as was affected at the end of 1889, and is probably referable to the same outbreak; whilst from March to June there were four cases in one family in another street; and, six months later, a more doubtful one in a third street of the same district. As to 1891, the report states that during the first nine months twenty-six cases were certified from fourteen different districts; but of these eleven proved not to be typhus fever and four others were doubtful. But at least twenty-four other persons suffered from typhus fever—not at first recognised. Particulars are given as to the chief cases, ten being certified at Holborn; but we have said sufficient to show that Mr. Murphy's opinion that typhus fever is evidently very ill recognised is justified, and we may especially draw attention to his admonition that "cases of ill-defined fever must be regarded with suspicion at the present time."

A WORKMEN'S SANITARY CONGRESS.

THE French labour party have determined that their Ninth Annual and National Congress shall be devoted to the discussion of one single subject. Up to the present all sorts of subjects have been discussed at these congresses, resulting in the proclamation of abstract principles and the adoption of ideal programmes. As everyone is now agreed as to the general principles that should govern the party, it is felt that something more precise and more practical should be attempted. The party has its representatives in Parliament, in the Paris Municipal Council, in the legal courts of arbitration, and in provincial local assemblies. These representatives should receive distinct instructions on practical legislative questions especially affecting the welfare of the working classes; and the annual Congress, instead of discussing a little about everything, has determined to devote the whole of its time to the careful study of one of these questions. It was of course somewhat embarrassing to decide which question should thus be considered, to the exclusion of all others; but it was ultimately resolved to give the preference to hygiene in its relations to the working classes. The debates of the Congress will be divided into three different phases of this great subject. First will be taken the problem of food-supply, especially in reference to the laws of March 27th, 1851, and May 5th, 1855. The workers will demand that the quality of the bread they eat shall be as carefully guaranteed by the State as the quality of the gold of which the current coinage is made. The second question relates to the sanitation of the worker's home, when the futility of the Commission on Unwholesome Dwellings will be dwelt on. The last subject is the sanitation of the workshop and factory, when the decree of 1810 will be denounced in no measured terms. According to this law the public

Digitized by Google

are protected against dangerous industries, but not the workers. Thus, lead works are put in the second category, because they do not give rise to injurious emanations, and are only injurious to the workmen themselves. Such will be the general scope of the Congress; but before the delegates of the trade unions and the workmen's societies who form the labour party discuss these problems they will invite the best known scientific authorities on hygiene to deliver addresses to the Congress so as to enlighten the delegates as to the technicalities at issue. This precautionary measure is at once as wise as it is modest, and denotes considerable discretion and tact on the part of the workmen. They will find a scientific basis for their demands and make their wants known to men of science. Thus the sympathy that already exists between workers with the brain and workers with the hand may be further developed, and to the great advantage of public health.

POSITION OF THE NOSE.

DR. SIMONTON, in the *Chicago Journal*, calls attention to the fact that the human nose is frequently not in the centre of the face, and he emphasises the importance of this fact with reference to the accurate fitting of glasses. The difference in the breadth of the two sides varies from one-sixteenth to one-eighth of an inch, but he has not found it more than an eighth. But such a difference, he says, is sufficient to cause much trouble and inconvenience, especially with somewhat high refractive errors, unless the glasses are accurately ground with reference to the actual position of the pupil. Any adaptation of the spectacle frame, he says, would upset their balance, so that the glass should be modified, if such an inequality, as he says is not uncommon, should exist.

DOES INFLUENZA PROTECT FROM A SUBSEQUENT ATTACK?

THE question whether an attack of influenza confers protection from subsequent infection is one which must have often arisen during the experiences of the last three years, but the data for its solution are not yet fully available. The amount of information which must have been gleaned by the family practitioner in all parts of the country upon this and many other points concerning the malady would, if collated, go far to settle the matter. It is of course notorious that certain individuals have suffered from more than one attack; but the conviction is pretty general that such cases really form but a small minority of the large numbers who have suffered. Then, again, it must be deemed possible that the degree and duration of the protection may depend on the severity which the primary attack exhibited, for one can hardly invoke the doctrine of attenuation of virus in the case of this disease, which shows so much variation from the ordinary course of infective disorders in general. In a highly interesting contribution upon the features of the present epidemic in Berlin, Dr. Ruhemann[1] directs especial attention to this question of protection and affords valuable evidence of it. He aptly remarks that the more gradual evolution and persistent character of the present epidemic, as compared with the rapid and stormy course of the pandemic of 1889 to 1890, have afforded opportunity for more closely studying the characters of the malady, and that it has especially enabled us to recognise more clearly its contagious nature. According to him influenza has prevailed in Berlin ever since the beginning of last September, and he notes how on this occasion the stress of the outbreak has fallen to a far greater extent upon women and children and less upon men than was the case two years ago. His own practice affords proof of this, especially in the fact of the greater frequency of uncomplicated cases among women than among men. As to the question of protection, he has observed that members of families who were severely attacked two years ago have either escaped entirely at present or been only slightly affected; whilst, conversely, the most serious cases of the present time have arisen in households which the influenza spared during its earlier visitation. He notes the statement of Dr. Edw. Gray,[2] to the effect that "many persons who escaped the epidemic of 1775 were affected by that of 1782, and many who escaped the latter were affected by the former," as showing that a century ago this question of immunity had not passed unnoticed. Dr. Ruhemann gives his own experience of 55 families, numbering 193 individuals. In 1889–90 there were 64 cases of influenza among this group, whilst in the present outbreak only 40 have been attacked, and, what is of especial interest, only 5 out of this number were affected (and that but slightly) two years ago, whilst of the 64 then attacked, only 4 have again become victims. Should this prove to be anything like the general experience it would go far to substantiate a fact that has hitherto been much disputed, even to the extent of declaring that one attack predisposes to another. That one individual may have several recurrences during the prevalence of a single epidemic does not, in Dr. Ruhemann's opinion, militate against the general doctrine of protection, since he thinks many such recurrences may be explained by lack of caution on the part of patients against exposing themselves to fresh infection before they are restored to full health. That influenza does protect from a second infection should reassure many persons who, having once suffered severely from it, dread a repetition of so depressing a malady; and it may be a further comfort to them to learn that the more they have suffered at first, the less likely are they to suffer at all again. If, then, influenza shares this common property of all infective diseases, it is not so remarkable that it should not apparently select the young in preference to the adult and aged, seeing that the whole community is more or less "unprotected" when it first reappears after an absence (in pandemic form) of years.

[1] Deutsche Med. Wochensch., Jan. 28th.

THE MANCHESTER MEDICO-ETHICAL ASSOCIATION.

WE have been favoured with the forty-fourth annual report of the Manchester Medico-Ethical Association. It reports "a spirit of activity" in the work of the Association. By way of increasing the interest of members and usefulness of the Association, the committee ventured to initiate an extension of the usual programme by securing a series of papers on the following questions of public interest:—A Presidential Address on Infant Mortality, by Dr. Ashby; the Disposal of the Dead, by Dr. Wahltuch; the Relation of Unhealthy Dwellings to the Etiology of Phthisis, by Dr. T. Harris; the Influence of the Drink Traffic on the Death-rate, by Mr. Meacham; and the Laws and By-laws regulating the Sanitary Arrangements of the City of Manchester, by Dr. J. Tatham. The attendance at the reading of these papers was very good. The committee took an active part in opposing the Midwives' Registration Bill, and in drawing attention to serious defects in the Factory and Workshop Act. On the subject of increased representation of the profession on the Medical Council the subcommittee suggested that it should be secured rather by some of the Crown nominations being given to members of the profession in general practice than by mere addition to the numbers of the Council. Not the least interesting question mooted in the Society was that

[2] Thompson's Annals, p. 110.

Digitized by Google

of establishing a black list. The question was referred to a subcommittee, which took counsel's opinion thereon. The subcommittee consider counsel's opinion to be in favour of such a list, but they think that it will require to be so carefully drawn up that the whole question should stand over for consideration next session. The profession will await with interest the further action of the Association in this delicate matter.

A LIFE FOR A LIVING.

AFTER another period of remarkable abstinence, lasting to within a few hours of forty-four days, and maintained in spite of gastric irritation, severe cold, London fog, and the indifferent atmosphere of his apartment, the Italian Succi, has found it needful to give way to nature, and to forego the last week of his self-allotted fast. We have no regret for this result, but rather for the fact that he will still persist in enduring for a time a modified starvation on lemons, oranges, and water. During the period above mentioned he has lost almost a third of his body weight, and has, it is clear, come within a hair's breadth of actual suicide. Why? For this is the essence of the question whether such performances are justifiable or not. For the settlement of scientific doubts, shall we say, or the proof of moral supremacy over appetite? No, these ends have already been attained by precise methods of research and by personal experience. If, therefore, such excuses be urged in the present connexion, we need not look far for the means of refuting them. The fasting man, as we now find him, is no recluse or companion of a few skilled observers merely. He is the constant notoriety of show companies, the central interest of curious crowds, and, finally, the sharer in substantial money profits. With him abstinence is a mere business, needless and dangerous in itself, detrimental to the discharge of more fruitful duties, and certainly not elevating to the moral sense of onlookers. As much may be said of the woman reported to be similarly employed in Paris. The prohibition of such disgraceful and inexcusable exhibitions would be nothing less than a public benefit.

THE DEATH-RATE IN GREATER MANCHESTER.

DURING the year 1890, when the death-rate in the city of Manchester, as it then existed, was for a considerable time above the high rate of 30 per 1000, the efforts of the Corporation to extend its limits were crowned with success. This success afforded the opportunity to certain ill-advised persons to declare that the high death-rate was merely a fallacy, mainly due to the artificially restricted boundaries of the city, and to assert that this extension would so reduce the death-rate as to prove that the excess of Manchester mortality, about which so much fuss had been made, was merely the result of a faulty system of mortality statistics. The extension came into operation, so far as the vital statistics of the city were concerned, on Jan. 1st, 1891, and its effect was to add to the population under the sanitary control of the City Corporation more than 100,000 persons. It will not be without interest to refer briefly to the mortality statistics of what has been called Greater Manchester for the year 1891, and to compare it with the figures relating to Old Manchester for preceding years. This interest will not be lessened from the fact that in certain local quarters much jubilation has been expressed because the Manchester death-rate has in recent weeks compared much more favourably with the rates in the other large English towns than was the case in 1890, before the last city extension. This, as can easily be proved, is not due to any remarkable decline in the recorded death-rate of Manchester, but to the fact that so many of the large towns have in recent weeks been suffering severely from the direct and indirect effects of the present influenza epidemic, from which, so far, Manchester has been comparatively free. The Registrar-General's quarterly return for the last three months of 1891 enables us to state that the death-rate of Greater Manchester was last year equal to 26·5 per 1000, which, although 3·2 per 1000 below the disastrously high rate in 1890, was only 0·1 below the mean annual rate in Old Manchester during the ten years 1881-90. It would have been thought that such an infinitesimal result on the death-rate from the inclusion of so large a suburban area within the city would have been a serious discouragement to those who never tire of writing on the so-called "fallacies about our death-rate." This discouragement becomes the more serious when it is admitted that the inclusion of this large suburban population cannot have been without effect in reducing the death-rate, from which it follows that the death-rate in Old Manchester last year must have been, if not as high as in 1890, considerably above the mean rate in the ten years 1881-90. The death-rate from "fever" (mainly enteric or typhoid), as well as from diphtheria and from whooping-cough, was considerably higher last year in Greater Manchester than the mean rates from the same diseases in Old Manchester in the ten preceding years. So with infant mortality, which was equal to 192 per 1000 births last year in Greater Manchester (although the diarrhœa rate in 1891 was low), whereas in Old Manchester the mean rate of infant mortality during the ten years 1881-90 was 179 per 1000, a rate far in excess of the rate in most of our other large towns. If we compare last year's death-rate in Greater Manchester with that in Greater London, the result is not more satisfactory to those who have to live in Manchester. The Greater Manchester rate was, as we have stated, 26·5 per 1000, while in Greater London the rate was only 19·6. This signifies that during last year, of equal numbers living, 135 persons died in Manchester to each 100 dying in London. To those who can read aright the logic of these figures, last year's mortality statistics of Greater Manchester abundantly prove that there is no fallacy in the excess of Manchester mortality. We shall look with much interest for Dr. Tatham's report on the health of the city in 1891, which will probably throw some useful light upon the local assertions that the high death-rate of the city is merely the result of fallacy.

CASE OF SHOCK FROM A TELEPHONE WIRE.

DR. JOSEPH COLLINS relates in the New York *Medical Record* a curious accident which happened to a patient of his. The latter was a man of thirty-one, who in September, 1890, was engaged in repairing a telephone wire, and while so engaged he received a shock through having touched a wire at a point where it had become accidentally uninsulated. He said that for two or three seconds he retained consciousness, and at this time he had no pain, but a sensation that he was filled with something, and a conviction that as soon as that sensation ceased he would die. He lost consciousness, fell down about twenty-five feet, and struck on a butcher's cart between the wheel and the body of the vehicle, thence falling to the ground on his head and neck. On recovering consciousness, which he did in a very short time, he was a little dazed. He had great weakness of his shoulder, and this became worse. At first the faradaic reaction was retained in his deltoid, but it disappeared later, and again returned, and he regained the use of his shoulder. He subsequently, however, developed numbness of one side and hemi-anæsthesia—a condition apparently functional in character, from which he recovered after being hypnotised. After the accident he also had two large burns, one on the left side of his neck and the other

Digitized by Google

on the postero-internal surface of the upper third of the tibia, these being apparently the result of the actual contact of the wires. The paralysis of the deltoid was no doubt due to an affection of the circumflex nerve, but there seems to be no reason for connecting this in any way with the electric shock. It is with more likelihood to be regarded as a result of the fall upon the shoulder.

WORKHOUSE INFIRMARY NURSING ASSOCIATION.

THIS Association was begun in 1879 with a view of, among other improvements, securing the appointment of trained ladies as matrons in all separate infirmaries, and to train and supply nurses to workhouse infirmaries in London and the provinces. The committee, consisting principally of gentlewomen, call attention to the importance of employing trained ladies as matrons in these institutions, and to the advantages which would accrue to the infirmaries if a system of training probationers in the general wards, and also in the lying-in wards of the infirmaries, were adopted in each. By a trained nurse is understood a person who has received at least one year's training in some approved general hospital or infirmary. Three years' training and experience in an institution for the sick is, in the opinion of the committee, very desirable for charge nurses. The committee have also formulated some very obvious axioms on the nature and effects of permanent night-nursing duty, and they make suggestions thereupon. The hours of daily recreation of nurses are, it is proposed, to be altered, on moral and hygienic grounds, from the evening to the afternoon.

INFLUENZA AND SALICIN.

IN the *Nineteenth Century* Dr. T. J. Maclagan has written an article under the above heading, and as it is sure to be widely read and eagerly discussed, it may be well to give in these columns some idea of the way in which the subject is treated. The conclusions may be very briefly stated—viz., that the poison of influenza is of malarial origin—a miasm, and therefore an organism; that there is not a little evidence to show that salicin in full and frequent doses cures influenza more rapidly than does any other mode of treatment, and that salicin seems also to exercise some protective influence, "ten grains three times a day for many weeks" being the dose recommended for this purpose. These conclusions are, however, preceded by many pages of matter even more open to criticism. In popular form the writer endeavours to explain the mysteries connected with the evils wrought by the reproduction of organisms within the body, and also to demonstrate that, even in the absence of microscopic proof, the belief in the existence of organisms may be derived from a study of the natural history of the diseases to which they give rise. In the course of his argument he mentions briefly the phenomena connected with the rapid reproduction of minute organisms, citing malarial fever, pneumonia, and rheumatic fever. Then he explains that the locality in which each parasite finds the special something required for its growth is technically called its nidus, and states that the time required for the exhaustion of the nidus varies in different diseases, but that the nidus, once exhausted, is, as a rule, never replaced. Here the desire to be lucid has led to error. One attack of rheumatic fever rarely stands alone, as it should do if the nidus were exhausted; and, moreover, with regard to pneumonia, it would be surely rather slipshod pathology to speak of a lobe of the lung as a nidus which, once exhausted, is never to be replaced. In further elaborating this view, he states that "the nidus of the poison of typhus fever is exhausted at the end of two weeks, and that if we can keep the patient alive for that time he will recover. We know that in typhoid fever it takes three weeks to exhaust it, and if we can tide the sufferer over that time he will get well." Would that this were true! Although Dr. Maclagan finds it necessary to speak thus hopefully of the later weeks of typhoid fever, experience does not confirm this. It is to be regretted that Dr. Maclagan's conclusions were not submitted for discussion in the medical journals, rather than in a lay publication, and without being encumbered with so much hasty and debateable material.

DEATH OF SIR MORELL MACKENZIE.

WE regret to announce the death of Sir Morell Mackenzie, which occurred suddenly on Wednesday evening at 10 P.M., at his residence in Harley-street, from syncope, following an attack of influenza. He was the most distinguished laryngoscopist in this country, and his practice was very extensive. When in his twenty-sixth year he was awarded the Jacksonian prize by the Royal College of Surgeons for his essay on the pathology and treatment of diseases of the larynx. Sir Morell Mackenzie attended the late Emperor Frederick, and it was in recognition of his services on that occasion that the Queen in 1887 bestowed on him the honour of knighthood. The Emperor also conferred on him the Grand Cross and Star of the Hohenzollern Order.

NOTIFICATION FEES AT CHELSEA.

A DISCUSSION that will require much justification has been raised in the Chelsea Vestry on the following motion: "That the question of payments of fees by the parish of Chelsea under the Notification of Diseases Act be referred to the Law Reference and Sanitary (Joint) Committees to take into consideration if some steps should not be taken to prevent some medical men in the parish from making returns that are considered unsatisfactory." It appeared to him most astounding that, from the figures published, practically three gentlemen received all the cases of infectious diseases in the parish. The mere fact that certain medical men have a larger number of infectious cases than others is not very remarkable. It is not much more so that a medical man should have more—perhaps double the number—in one quarter than in another? One of the speakers seemed to blame more those who do not report than those who report so many. It is difficult to please the Chelsea Vestry.

PENTAL AS AN ANÆSTHETIC.

BRENER, in a communication to the Royal Medical Society of Vienna, reports having used pental as an anæsthetic 150 times in his dental practice. Loss of sensation is produced before complete loss of consciousness. Usually the patient recovers quickly and easily. The effect is produced generally in one or two minutes, and requires ten to fifty grammes. According to Rogner in the *Wien. Med. Pr.*, 1891, and Hollander in *Nouv. Rem.*, 1891, the loss of sensation lasts about four minutes, and towards the end of the seventh minute passes away. There is no vomiting or other troublesome symptom during the inhalation, nor does headache or sickness occur afterwards. The loss of consciousness comes on during the first few minutes with complete loss of voluntary movement. Rogner considers it the best anæsthetic to use in minor surgery. In spite, however, of these favourable reports, Brener himself had a serious accident. A girl who required extraction of a tooth was placed under the effect of pental. She had only taken four grammes when alarming symptoms arose—syncope, apnœa, loss of pulse, and dilatation of the pupil. It was necessary to resort to artificial respiration to restore con-

Digitized by Google

sciousness. This fact, as Basch and Dittel observe, proves that new anæsthetics, and especially those producing rapid narcosis, require great care in their employment.

A SANITARY ASSOCIATION FOR LEEDS.

THE sanitary condition of Leeds has attracted a good deal of local attention and comment, and under the support of the mayor, Dr. Cameron the medical officer of health, and many other prominent citizens, a meeting was convened last week, at which it was decided, on the motion of the vicar of Leeds, to form an association to coöperate with the sanitary authorities for securing improvement in the circumstances of the borough. The objects of the association as at present formulated will be to influence public opinion in Leeds on sanitary matters, to assist in bringing sanitary deficiencies to the knowledge of the proper authorities, and generally to promote sanitary improvements in the borough. The assistance of ladies is also to be secured. The association will, in all essential respects, resemble the parent one in Manchester and Salford, an association which has done much good, and which has always secured the hearty coöperation and support of the medical officers of health of the two important communities in which it has laboured.

ROYAL COLLEGE OF PHYSICIANS.

AT a meeting of the Royal College of Physicians, held on Thursday, Jan. 28th, the following gentlemen were nominated to act as a Committee for the Revision of Nomenclature of Diseases, a work which is undertaken by the College of Physicians every ten years. Besides the President (Sir Andrew Clark) and the Registrar (Dr. Edward Liveing) (*ex officio*), the committee will consist of Dr. Bristowe, Dr. Hermann Weber, Dr. Pavy, Sir W. Roberts, M.D.; Dr. Buchanan, Dr. W. Ogle (London), Dr. Gee, Sir Dyce Duckworth, M.D.; Dr. Stevenson, Sir Joseph Fayrer, Dr. R. Liveing, Dr. T. Buzzard, Dr. J. F. Payne, Dr. D. Hack Tuke, Dr. Thorne Thorne, Dr. Ord, Dr. Cavafy, Dr. T. Lauder Brunton, Dr. Frederick Roberts, Dr. Sansom, Dr. Galabin, Dr. Champneys, Dr. Dreschfeld, Dr. Savage, Dr. Tooth, Dr. Greenhill, and Dr. Perry of Guy's Hospital, with power to add to their number. Certain surgeons have also been invited to assist the College in the carrying out of this work, but their names have not yet been made public.

INFLUENZA IN CHILDREN.

THERE seems to be a prevailing impression that infants and young children are not attacked by influenza. That this idea is wrong, however, many practitioners can testify; it is naturally difficult to diagnose in such patients, but the fact that they sicken when their parents or nurses are affected with the disease is strong presumptive evidence that they also are attacked. Dr. David Fuchs of Budapest is of this opinion, and publishes a short article on the subject in the *Allgemeine Wiener Medicinische Zeitung* of Jan. 19th of this year. He states that he has met with many cases of influenza in young children, but that the symptoms and course of the disease differ in some particulars from those occurring in the adult. As a rule the attack is lighter. It commences with fever, and the onset is sudden. One day the child may be perfectly healthy, whilst on the next it is severely ill without any prodromal symptoms having developed. The temperature does not generally rise above 103° F., though it may occasionally be as high as 104°. After lasting twenty-four hours the fever commences to subside. With many children cerebral symptoms predominate. Dr. Fuchs records one case in which a child, aged eighteen months, was without any warning seized with severe laryngeal symptoms, followed by convulsions, whilst the temperature rose rapidly to 104°. Vomiting is a very common symptom. Next in frequency come affections of the mucous membranes. The conjunctivæ are injected, and there is catarrh of the throat and nasal passages. In this stage the general appearance is very similar to the early stages of measles. The tongue is coated, and the child gradually subsides into an apathetic state. Older children complain of severe headache. The bowels are usually confined. There is not unfrequently a peculiar rash; it appears on the trunk and lower limbs, and takes the form of small papules not unlike the exanthem of varicella. Its extent varies greatly, and the number of spots may be very few or the reverse. In one child eighteen months old a few small pemphigus vesicles appeared on the backs of the legs, which were at first filled with a clear fluid, but afterwards dried up. Bronchial catarrh, usually slight, frequently follows. After these symptoms have lasted a few days, the temperature becomes normal, and the inflammation of the conjunctivæ and nasal mucous membranes disappears. The other catarrhal phenomena last longer, and the troublesome cough is difficult to get rid of. The exhaustion is considerable, and even after an illness of only three days a strong child will be very much pulled down. The prognosis is in nearly all cases favourable. Although weakly children suffer more than those who are stronger, serious complications rarely set in, and pneumonia is but rarely met with. The treatment is symptomatic, and Dr. Fuchs advises that no antipyretic drugs should be given, as they only tend to depress the patient. He recommends isolation.

DEATH CERTIFICATES BY UNQUALIFIED ASSISTANTS.

THE borough coroner for Hanley, on Jan. 29th, after an inquest on Mrs. Emma Harvey, who had been attended by Mr. Austerberry, Mr. Arthur Goodwin's unqualified assistant, who also filled up the death certificate in Mr. Goodwin's name, expressed his intention to report the circumstances to the General Medical Council. Mr. Goodwin had never seen the deceased. The registrars are showing a proper care in this serious matter. In this case the registrar, Mr. Hammersley, knowing that Mr. Goodwin was ill, scrutinised the signature, and found it was not in his handwriting. We trust Mr. Goodwin will be able to show that he was in no way responsible for this action of his assistant. It is amazing, after all that has happened in similar cases, that unqualified assistants should still be found to run such risks.

POISONING BY HYOSCINE.

DR. ADLER of Breslau publishes particulars of a case of poisoning by hyoscine. A man employed in the chemical laboratory used a glass for drinking purposes which contained a deposit of hydrochlorate of hyoscine. In a quarter of an hour he was attacked with vertigo, and gradually became unconscious. An hour and a quarter after taking the poison he was seized with convulsions, and rapidly became comatose. Upon arrival at the hospital he was found to be suffering from trismus, with occasional clonic spasm of the muscles of the lower jaw and of the limbs. The stomach was washed out, but no traces of hyoscine were found in the fluid withdrawn. Two centigrammes of morphia were immediately given hypodermically, after which the convulsions ceased, but the rigidity lasted until five o'clock in the evening. A hypodermic injection of one centigramme of pilocarpine was then given, but the effect of it was not apparent until three o'clock next morning, when the coma had given way to a drowsy condition and the pulse had dropped to 104. At 5 A.M. the patient was able to answer questions. He, however, became extremely rest-

Digitized by Google

less and excited. He was put under the effect of chloroform, and in a quarter of an hour he slept quietly. On waking he complained of great weakness, his gait was uncertain, and his pupils widely dilated. His urine contained hyoscine. He eventually entirely recovered.

ROYAL COMMISSION ON TUBERCULOSIS.

A MEETING of this Commission was held at 7, Whitehall-place, on Feb. 28th. Lord Basing occupied the chair, and there were present Professor Brown, Dr. Buchanan, Dr. Payne, Professor Burdon-Sanderson, and Mr. Leopold Hudson (secretary). The directors of the experimental investigations which are being undertaken as to the infectivity of tubercle and the ability of cooking processes to destroy such power of infection presented progress reports, and the results to date of the various inquiries which are being conducted were considered.

EFFECT OF ALKALIES ON METABOLIC CHANGE.

As the effect of alkaline drugs upon the nature of the metabolic changes which albumen undergoes in the system has not been satisfactorily worked out, Dr. Yavein has made a series of elaborate observations on the subject, employing citrate and carbonate of soda for the purpose. The daily quantities of the drugs administered were 300 grains or more. The results showed as a rule that there was but little effect either on the assimilation or on the metabolic change of albumen. There was, however, a considerable increase in the neutral phosphates as compared with the acid phosphates of the urine. As a rule, the loss from the skin and lungs was diminished, and after the alkali had been discontinued the quantity of urine increased. The body weight increased while the alkali was being taken, and decreased afterwards, the increase being probably due to the diminished loss of moisture, and the decrease to the augmented secretion.

A CASE OF POISONING BY PILOCARPINE.

A BELGIAN OFFICER with an affection of the eyes was treated by the injection of two centigrammes of this drug. Immediately his neck and then the whole of the body became bathed with sweat, in two or three minutes he was salivated, and suffered from cardiac oppression and difficulty of breathing, he fancied his chest was full of fluid, and afterwards he expectorated some frothy mucus. The cardiac oppression lasted about ten minutes, but for two hours the patient continued to have a feeling of constriction at the pit of the stomach. During this time he suffered from lacrymation, running from the nose, gastralgia, and nausea; he vomited three times, and passed his urine involuntarily. The intestinal peristalsis became violent and he had tenesmus. His eyes were fixed, and he could not recognise anyone twenty centimetres distant. The pulse was quick and small, the sufferer being in a condition bordering on collapse. By means of internal and external stimulants the symptoms disappeared.

INFLUENZA IN HAMPSTEAD.

AN opportune report on the epidemic of influenza has been issued by Dr. Gwynn, the medical officer of health for Hampstead. In it he refers to the fact that the fatality as yet attributed to that disease has not nearly reached the point attained by the epidemic in the spring of 1891; and as regards London generally, he reminds us that the week in which the death-rate rose to its highest contributed only thirty-seven deaths registered as due to influenza, the actual deaths rising in four weeks from nineteen to 271, whereas in the same period the lowest number of deaths from whooping-cough was ninety-three, with a subsequent rise to 180, and this without exciting much comment. This bears out our remarks of last week with regard to the relation between the deaths from influenza and measles respectively. In the end, Dr. Gwynn advises that panic should be avoided, and he considers that it would be undesirable to deal with influenza as a dangerous infectious disease for the purposes of notification. In this we agree with him. The clinical features of the disease cannot be sufficiently differentiated from a number of other ailments, some of a comparatively trivial character, to justify any proceedings for non-compliance with the Act, and so long as this is the case it can hardly be right to bring it within the scope of a penal statute. At the same time Dr. Gwynn issues some useful suggestions as to precautionary measures which it is desirable to adopt.

SIR GEORGE PAGET, K.C.B., M.D., F.R.S.

BY the death from influenza of Sir George Paget on Friday, Jan. 29th, the University of Cambridge suffers a grievous loss. Born on Dec. 22nd, 1809, he entered as a student in the year 1827 at Gonville and Caius College, and in 1838 was created a Doctor of Medicine. In the year following he was elected a Fellow of the Royal College of Physicians. In 1869 he became President of the General Medical Council in succession to the late Sir George Burrows, and in 1872 the appointment of Regius Professor of Physic, vacant by the death of Dr. Bond, was conferred by the Crown on Dr. Paget. With his appointment the medical school at Cambridge began to rise in estimation and its degrees in worth, a change attributable to the perseverance and energy of Sir George Paget and of Sir George Humphry. He was an indefatigable worker. His bust adorns the meeting room of the General Medical Council. In 1886 he was created a K.C.B. His punctuality, charming manner, extensive experience, and skill endeared him to all with whom he was brought in contact. We reserve a detailed account of his labours for our next issue.

SMALL-POX OCCURRENCES.

SMALL-POX is somewhat prevalent in several northern districts. In addition to the prevalence at Batley, to which we have previously adverted, ten cases have been admitted to the Liverpool small-pox hospital; a case from Morley has been received into the Leeds isolation hospital; and several cases have occurred at Wakefield, where a magistrate's order was obtained to remove some cases to hospital, including a convalescent, and to prevent the sale of milk and butter from the premises in question.

DEFLECTIONS OF THE NASAL SEPTUM.

IN a paper recently read before the British Laryngological Society Mr. Mayo Collier very strongly contended, and his contentions were received with unanimous approval, that deflections of the nasal septum were almost always due to a difference in pressure on one side of the nasal septum, due to the blocking of one nostril, and to consequent aspiration of the closed cavity by the stream of air passing through the naso pharynx from the open one. From the examination of over 1000 living subjects 90 per cent. showed some deflection or other irregularity of the nasal septum; savages and aborigines only to the extent of 20 per cent.; children under ten years not at all; but from ten to sixteen blocking and consequent deflection were most easily induced from the more frequent occurrence of injury to the small dilators of the nose, and their consequent paresis or paralysis.

FOREIGN UNIVERSITY INTELLIGENCE.

Geneva.—Dr. Frœlich has been recognised as *privat-docent* in Ophthalmology.

Gratz.—Professor J. Kratter of Innsbruck has been

Digitized by Google

appointed to succeed Professor Schauenstein in the Chair of Forensic Medicine. He has published several researches in hygiene, toxicology, and medical jurisprudence.

Montpelier.—Dr. Carrieu, Professor of Internal Pathology, has been appointed Professor of Clinical Medicine.

Naples.—The University has been closed for the present by the Minister of Education in consequence of a disturbance created by some of the students. This does not seem to have been perpetrated by medical students, though they have to bear the punishment as well as their colleagues. A strict inquiry is being made by Government officials.

St. Petersburg (Military Medico-Chirurgical Academy).—Dr. Favitski has been recognised as *privat-docent* in Medicine, and Dr. Batuïeff as *privat-docent* in Anatomy.

WE are asked to state that it has been arranged to hold an evening class in Public Hygiene at King's College, to commence on Tuesday next at 8 P.M., and to be continued on Fridays and Tuesdays at the same hour. It has been thought that this step, which is, it is said, the first of its kind attempted in London, will be likely to meet the convenience of many medical practitioners who are unable to attend classes in the daytime.

THE managers of the Metropolitan Asylums Board have determined, with the sanction of the Local Government Board, to place the Ambulance Service at the disposal of the public for influenza patients, for their removal to places other than the hospitals of the Board. The charge for the hire of the ambulance, including, when the patient is over ten years of age, the services of a male attendant, is 5*s*.

THE committee of organisation of the International Congress of Gynæcology and Obstetrics, which will hold its first meeting at Brussels in September, have elected Dr. Benington, of Newcastle-upon-Tyne, as Assistant English Secretary to act for the North-east of England.

WE regret to notice the death of Mr. William Adams, F.R.C.S., J.P., of Regent's Park. Mr. Adams was well known in the metropolis, and not infrequently attended the meetings of the Clinical and Pathological Societies, of which he had long been a member.

THE FRENCH GOVERNMENT SANITARY BILL.

IT has already been announced that M. Constans, Minister of the Interior, on behalf of the French Government has introduced in the National Assembly the project of a sanitary law. We have now before us the text of this Bill, and must confess that it seems a somewhat raw measure, which will require considerable improvement before it can be considered as completely satisfactory. Nevertheless, it is encouraging to see the French Government take the initiative in this matter, and some of the provisions of the Bill are excellent. Article 1 stipulates that when a commune is in need of sanitary works, or has not a sufficient supply of good potable water, the prefect shall invite the Departmental Council of Hygiene to deliberate and report on the nature of the sanitary works required. If the report does not agree that such works should be undertaken, it shall be forwarded to the Minister of the Interior, who, if he thinks it necessary, shall submit the matter to the Consulting Committee of Hygiene for France. If either the County Council of Hygiene or the National Consulting Committee of Hygiene decide that such sanitary works must be undertaken, then the prefect shall order the commune to carry out these measures. If such works are not commenced within three months, then they shall be taken in hand by the Government, though the commune will have to pay the entire cost, according to the law of Sept. 16th, 1807. At present the mayors of communes theoretically possess very extensive powers, but practically they dare not exercise these powers unless it be under the stress of some great epidemic. Now, however, it is proposed to give both the provincial authorities, and then the national or central government, the right to interfere, and bring the necessary pressure to bear on each locality. In other words, the object of the Bill will be to give the State the right to stimulate the local authorities who are unmindful or ignorant with respect to their duties. Article 2 of the Bill deals with domestic hygiene. When a house is considered unhealthy the mayor must call upon the local commission of hygiene to report and suggest the necessary improvements. If the report is opposed to any measures being taken, the mayor shall refer the matter to the higher authorities—i.e., the prefect or the Departmental Council of Hygiene. If either of these superior authorities approve, the mayor shall call upon the householder or the tenant to commence within eight days the necessary alterations. But there follow clauses by which appeals can be made against such decisions, though these appeals will be less expensive and more expeditiously settled than under the present laws. There is also a clause by which, if it is thought impossible to render a house wholesome, it may be closed by the mayor and declared unfit for habitation. Article 3 deals with insanitary areas, giving the communes the right of compulsory purchase, demolition, and reconstruction of such districts. Article 4 stipulates that no building can be erected unless the mayor approves of the system of drainage proposed; and no such new building can be inhabited till the local sanitary authority has viewed and approved the work done. Articles 5 and 6 deal with the contamination of water-supply, the surveillance of cesspools, &c., and Article 7 imposes the obligatory declaration of all cases of infectious disease within twenty-four hours. The declaration is to be made by the doctor or the midwife; and, in default of either, by the relatives or those in charge of the sick person. Article 8 will establish for the first time in France obligatory vaccination, and this not only for infants, but it also enforces revaccination at the tenth and at the twenty-first years. Articles 9 and 10 deal with the drawing up of a code of rules in each district for the prevention of disease. The following articles of the project describe the constitution and duties of the local and central committees or councils of hygiene, and the last—that is, the 18th—article abrogates the law of April 13th, 1850, and all other previous laws which are in oppositon to the present project. This last clause is most important. It is because the Belgian law is the same as the French law, minus the law of 1850, that such notable sanitary improvements have been successfully accomplished in Belgium, and especially in Brussels.

The Bill, it will be seen, is very short, and it seems extraordinary to provide for the sanitary legislation of a large country in eighteen articles. Among the many omissions we note the absence of any machinery for sanitary inspection. There are no clauses establishing medical officers of health, inspectors of nuisances, and surveyors. There are sanitary committees who may discuss cases submitted to them, but where are the functionaries to ferret out such cases? A committee of hygiene consists of doctors, chemists, engineers, architects, and notable and eminent inhabitants of the district, who are supposed to possess special knowledge of subjects relating to public health. These gentlemen will occasionally afford an hour or two to meet and discuss. As a sort of controlling committee, and more especially as a means of educating public opinion in matters of hygiene, they are very useful. But something more than this is urgently required. There must be medical officers and inspectors, whose sole business it shall be to work out the sanitary regeneration of the country.

PRESENTATION.—Mr. J. Harley Gough, L.R.C.P. Lond., M.R.C.S., has been presented with a case of surgical instruments by the nursing staff of the Royal Albert Hospital, Devonport, on resigning his appointment of resident medical officer, which he had held for upwards of two years.

THE EDINBURGH ASSOCIATION FOR THE REFORM OF MEDICAL EDUCATION.

PUBLIC MEETING IN EDINBURGH.

A PUBLIC MEETING of medical men and graduates interested in the reform of medical education was held on Monday last, Feb. 1st, under the auspices of the Edinburgh Association for the Reform of Medical Education. There was a large attendance of medical men resident in the city, more especially of the younger men, who are very earnest in their wish to see decided and radical improvement in the present methods of teaching. The chair was occupied by Lord Provost Russell, who is himself a graduate in medicine of Edinburgh, and was at one time a demonstrator of anatomy in the University, and is *ex officio* a member of the University Court. In his opening remarks he referred to the high position the University had attained, and to the fact that the citizens and the people of Scotland were proud of it. To maintain its high position it was necessary that it should advance with the times, and it was the recognition that such advance was necessary, and was not sufficiently provided for in the Draft Ordinances of the Commission, that the Association was called into existence. Changes in the methods of teaching and reforms very often meant alterations that apparently affected vested interests; but he thought it was quite possible to discuss such changes without making it appear that any injury was intended by changes proposed to be introduced at the instance of the Association.

Dr. Batty Tuke moved the first resolution, which was as follows: "That this meeting deems it essential that the Commissioners should insist on a diminution in the number of systematic lectures with a view to make room for practical work and demonstrations to limited numbers of students." In his speech supporting this motion he considered the causes which had led to the success of the University, and pointed out that the London schools had only recently realised the true cause of Edinburgh's success. One of the mainstays of Edinburgh University was the extreme conscientiousness and the perfect thoroughness with which their hospital men performed their work. He would challenge any school in Great Britain or abroad to produce active, busy, professional men devoting two or three hours a day to the education of the students in the hospital. He thought it would be admitted that practical teaching was essential to the educational spirit of the age, and their Association held that the practical system should be extended and the systematic lectures reduced. They were not the first to advocate this reform, for it was laid down by the General Medical Council of Education and Registration in a series of resolutions which were adopted in 1880. Practical teaching necessitated smaller classes, and this in turn necessitated a greater number of teachers.

Dr. C. W. Cathcart seconded the resolution, which was carried unanimously.

Principal Grant Ogilvie proposed the second resolution: "That an 'honours' school should be established, in which the more capable students may undergo a more extended training and present themselves for special honours examinations."

This resolution was seconded by Dr. Berry Haycraft, who pointed out that if the present ordinance of the Commissioners was retained they would be tied up for the next thirty years or more to a regulation curriculum and examination system through which good, bad, and indifferent students had alike to pass, and from which they would be turned out as so many machine-made articles. If in the future their Simpsons, Symes, Bruntons, and Ferriers were to be produced by English schools, they must give up the hope of keeping their University in the front rank of teaching institutions, and the loss of prestige would react on the mass of students. The way to avoid this was by arranging for a limited number of capable and ambitious men, and an extended and elastic curriculum, as complete, or more so, as any obtainable in the best English or foreign school.

This motion led to a good deal of discussion, which was introduced by Dr. Byrom Bramwell taking exception to the suggestion that for honours it would be necessary to go right through the whole special curriculum sketched for the honours school, and that a modification of the present system was more desirable. At the same time, he in other respects heartily agreed with the proposals of the Association, and held that the recommendations and alterations in the draft ordinance were altogether ineffectual and insufficient for the requirements of the case. His amendment was as follows: "That it is undesirable to interfere with the present system of giving honours, with the exception that the work required for the ordinary pass examination should in each subject be limited and defined by printed syllabus, an additional question or questions, not necessarily included in those portions of the subject specified in the pass examination syllabus, being added in each written paper for honours candidates, and the extent and severity of the *viva voce* and practical portions of the examination being, in the case of honours candidates, proportionately increased." Drs. McBride, Joseph Bell, William Russell, and Hoernlé took part in the discussion, and favoured the proposals of the Association, and on being put to the vote the original motion was carried by a large majority.

The third motion was submitted by Dr. G. A. Gibson: "That the meeting would strongly urge the necessity for allotting the last two years of study to the systematic and clinical work of the final subjects and specialties." This was seconded by Dr. Berry Hart. Both mover and seconder spoke strongly on the necessity of this, both from the student's standpoint and the public necessity of having men thoroughly trained in the practical study of disease. They also animadverted on the carrying on of materia medica and pathology to the end of the fourth year. This motion was also unanimously carried.

The last motion was proposed by Dr. G. A. Berry and seconded by Dr. Cadell, and bore upon the necessity of increasing the number of examiners, so as to give ample time for testing students' knowledge.

The meeting was altogether a very successful one, and the report of it which has appeared in the newspaper press has aroused very general interest throughout the city.

ARMY MEDICAL SCHOOL, NETLEY.

THE sixty-third (winter) session of this School was brought to a close on Monday, when the distribution of prizes took place, General Sir Frederick FitzWygram, Bart., M.P. for the Fareham Division of Hants, performing the interesting ceremony. The proceedings were carried but in the lecture theatre of the Royal Victoria Hospital, in the presence of a numerous gathering of ladies and of military and medical officers, including Surgeon-Major-General Lithgow, D.S.O., Surgeon-Major-General Tippetts, P.M.O. at Netley, Sir Joseph Fayrer, K.C.S.I., Professor Sir William Aitken, F.R.S., Professor J. Lane Notter, Surgeon-General W. C. Maclean, C.B., the assistant professors, Messrs. Bruce, Davies, Stevenson, and Whitehead, and the secretary of the School, Mr. Bouchert. There were also present Colonel Hanning Lee, Major Haldane, Major Stoke, Captain Attree, R.E., Acting-Adjutant Surgeon-Captain C. J. Addison, M.S. (by whom the surgeons on probation of both the Army Medical Service and the Indian Medical Service were marched up to the lecture theatre). Colonel the Hon. H. G. L. Crichton and Lady Emma Crichton, Lady Aitken, Mr. Bloxam, Mrs. Godwin, Mrs. Notter, Mrs. and the Misses Cayley, Mrs. Hayes, Miss Erskine, Mrs. Bruce, Mrs. Du Chaumont, Mrs. Davies, Miss Norman (lady superintendent of nurses), and a few of the nursing sisters.

Sir Frederick FitzWygram, after handing the prizes to the successful students, said that all medical charges were important and responsible, but none were more important or responsible than those of the medical officers of the army. In fact, he might say he knew of no medical charges so important or responsible, because in military medical life, especially abroad and in war, they would have to lean entirely on their own knowledge, skill, and practice. In civil life it was otherwise. In civil life, according to their aptitude and circumstances, they generally drifted into one particular line, and adopted surgery, medicine, or some special subject. But in the army they needed medical men who were well up in every branch of the best modern medical science. They needed, if he might use the expression, all-round men—a military medical officer who was

Digitized by Google

at once surgeon, physician, accoucheur, oculist, aurist, chemist, analyst, an expert in sanitary science, and, almost above all, a good nurse; one who could not only teach those under him, but who possessed the delicate art of ministering to the wants of the suffering. They needed the best and brightest students of their schools, and he hoped many of those he saw would well sustain, and, it might be, increase, the best traditions of the honour and skill of the Army Medical Department.

Sir Joseph Fayrer said it gave him renewed pleasure to come year after year and see the fresh young faces of those about to enter a new sphere of life.

Mr. Bloxam, one of the surgeons of Charing-cross Hospital, London, who twenty-five years ago was a student at Netley, expressed a wish, in his concluding remarks, that there were opportunities for surgeons after passing to come back to Netley for another course of work.

Sir Frederick FitzWygram referred to the matter touched upon by Mr. Bloxam. Medical officers when going on foreign service naturally lost touch with some matters, and he had suggested that on their return they should be allowed six months, on full pay, to study at one of the great hospitals. He thought if the heads of the department would follow up that idea there would be no difficulty in getting it carried out, and the plan would be of immense advantage.

INFLUENZA.

THERE can be, happily, no question that the epidemic of influenza is at length subsiding in this country, and although it still prevails with considerable severity in some districts, we do not hear of its extension to districts which have hitherto escaped; whilst the cases are diminishing in several counties that have been particularly attacked. The mortality returns for the week ending Jan. 30th substantiate this, for although next to Croydon (47·2 per 1000), London heads the list with an estimated death-rate of 41, yet the deaths directly attributed to influenza in the metropolis have fallen from 506 to 436, in addition to which there were 71 cases in which influenza was noted as a secondary cause. This may seem a slight decline, but we have little doubt that a much more marked fall will be recorded next week. There has *pari passu* been a decline in the number of deaths from respiratory diseases—viz., from 1465 to 1192, but the latter is 654 in excess of the corrected average. Brighton, we are glad to see, is rapidly recovering its normal death-rate, the returns showing the remarkable decline from a rate of 60·9 in the preceding week to one of 24·6. Indeed, the death-rate is lower this week in most of the thirty-three large towns quoted by the Registrar-General; but it stills remains abnormally high in Norwich (39·1), Blackburn (37·5), Birkenhead (34·0), and Liverpool (33·1).

Accounts of the subsidence of the epidemic come from South Kent, Surrey, Hants, and North Wilts, but there does not as yet appear to be any marked diminution in Essex, Norfolk, Northamptonshire, and Yorkshire.

On the Continent, it still prevails to a considerable extent in some parts of Germany, especially in Mecklenburg, and in Vienna it is said to be "alarmingly on the increase."

METROPOLITAN HOSPITAL SUNDAY FUND.

ARCHDEACON SINCLAIR presided at a meeting of the members of the Council of this Fund, held at the Mansion House on Tuesday last. The Lord Mayor was unavoidably absent. Mr. H. N. Custance, the secretary, announced anonymous donations of £500 and £50 respectively. Allusion was made to the loss by death of Sir J. Risdon Bennett and Cardinal Manning, who were valued members of the Council. The Chief Rabbi, Lord Sandhurst, Mr. Wakley, Mr. A. L. Cohen, Dr. Charles J. Hare, and Canon Ingram were elected to serve on the General Purposes Committee, in the place of several members who had died or who were unable to attend the meetings. Mr. H. C. Burdett moved the adoption of a uniform system of accounts for hospitals and dispensaries. The system proposed would, he said, be a great advantage, and it had been agreed to by secretaries of the hospitals and dispensaries interested in the Fund. Dr. Glover seconded the motion, and it was carried on the understanding that a suggestion by Mr. Acland, chairman of the Hospital Saturday Fund, to the effect that items should be separately put in the income accounts, showing the amount derived from workshop contributions and church parades, should be further considered.

Dr. J. H. Rigg moved, and the Chief Rabbi seconded, a vote of condolence to the widow of Mr. Spurgeon, who had frequently preached earnestly on behalf of the Fund. The vote was unanimously passed.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6227 births and 6275 deaths were registered during the week ending Jan. 30th. The annual rate of mortality in these towns, which had increased in the preceding three weeks from 28·7 to 35·4 per 1000, declined again last week to 32·1. In London the rate was as high as 41·0 per 1000, while it averaged 25·7 in the thirty-two provincial towns. The lowest rates in these towns last week were 18·4 in Sunderland, 19·2 in Halifax, 19·5 in Salford, and 19·8 in Birmingham; the highest rates were 34·0 in Birkenhead, 37·5 in Blackburn, 39·1 in Norwich, 41·0 in London, and 47·2 in Croydon. The 6275 deaths included 455 which were referred to the principal zymotic diseases, against 604 and 518 in the preceding two weeks; of these, 241 resulted from whooping-cough, 92 from measles, 39 from diphtheria, 34 from diarrhœa, 25 from "fever" (principally enteric), 24 from scarlet fever, and not one from small-pox. No fatal case of any of these diseases was recorded in Croydon, Brighton, Plymouth, Huddersfield, or Halifax, while they caused the highest rates in Swansea, Wolverhampton, Derby, and Blackburn. The greatest mortality from measles occurred in Derby, Newcastle-upon-Tyne, Wolverhampton, and Burnley; from scarlet fever in Cardiff and Swansea; from whooping-cough in West Ham, Swansea, Bolton, London, Bristol, Wolverhampton, and Derby; from "fever" in Blackburn; and from diarrhœa in Preston. The 39 deaths from diphtheria included 24 in London, 3 in Salford, 2 in Manchester, and 2 in Bristol. No fatal case of small-pox was registered in any of the thirty-three great towns; 7 small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and 2 in the Highgate Small-pox Hospital. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 1327, against 1391 and 1397 at the end of the preceding two weeks; 100 new cases were admitted during the week, against 92 and 116 in the previous two weeks. The deaths referred to diseases of the respiratory organs in London, which had been 1084, 1248, and 1465 in the preceding three weeks, declined last week to 1192, but exceeded by as many as 654 the corrected average. The causes of 94, or 1·5 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Norwich, Preston, Newcastle-upon-Tyne, and in six other smaller towns; the largest proportions of uncertified deaths were registered in Oldham, Blackburn, Sheffield, and Hull.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 23·9 and 27·2 per 1000 in the preceding two weeks, declined again to 24·7 during the week ending Jan. 30th, and was as much as 7·4 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 19·0 in Greenock and 19·1 in Paisley to 26·0 in Glasgow and in Leith and 30·2 in Aberdeen. The 687 deaths in these towns included 16 which were referred to whooping-cough, 7 to "fever," 6 to measles, 6 to diarrhœa, 4 to diphtheria, 2 to scarlet fever, and not one to small-pox. In all, 41 deaths resulted from these principal zymotic diseases, against 50 and 72 in the preceding two

Digitized by Google

weeks. These 41 deaths were equal to an annual rate of 1·5 per 1000, which was 0·8 below the mean rate last week from the same diseases in the thirty-three English towns. The fatal cases of whooping-cough, which had been 16 and 24 in the preceding two weeks, declined again to 16 last week, of which 6 occurred in Aberdeen and 5 in Glasgow. The deaths referred to different forms of "fever," which had been 6 and 5 in the previous two weeks, rose to 7 last week, and included 4 in Glasgow. The 6 fatal cases of measles showed a decline of 5 from the number in the preceding week, and included 5 in Glasgow. The deaths from diphtheria, which had been 5 and 9 in the previous two weeks, declined again to 4 last week, of which 2 occurred in Glasgow and 1 each in Leith and Greenock. The 2 fatal cases of scarlet fever were considerably below those recorded in any recent week, and included 1 in Aberdeen and 1 in Paisley. The deaths referred to diseases of the respiratory organs in these towns, which had increased in the preceding three weeks from 200 to 230, declined again last week to 211, and were within 4 of the number in the corresponding week of last year. The causes of 69, or nearly 10 per cent., of the deaths in the eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had increased in the preceding three weeks from 35·0 to 54·1 per 1000, declined again to 41·5 during the week ending Jan. 30th. During the first four weeks of the current quarter the death-rate in the city has averaged 43·6 per 1000, against 40·0 in London and 22·2 in Edinburgh. The 278 deaths in Dublin during the week under notice showed a decline of 85 from the exceptionally high number in the preceding week, and included 5 which were referred to whooping-cough, 3 to "fever," 1 to diarrhœa, and not one either to small-pox, measles, scarlet fever, or diphtheria. In all, 9 deaths resulted from these principal zymotic diseases, equal to an annual rate of 1·3 per 1000, the rate during the same period being 3·2 in London and 0·8 in Edinburgh. The fatal cases of whooping-cough, which had been 5 and 10 in the preceding two weeks, declined again to 5 last week. The deaths referred to different forms of "fever," which had been 2 and 5 in the previous two weeks, declined to 3 last week. The 278 deaths registered in Dublin last week included 32 of infants under one year of age, and 105 of persons aged upwards of sixty years; the deaths both of infants and of elderly persons showed a marked decline from the very high numbers recorded in the preceding week. Four inquest cases and 5 deaths from violence were registered; and 80, or more than a fourth, of the deaths occurred in public institutions. The causes of 26, or more than 9 per cent., of the deaths in the city last week were not certified.

CALCUTTA AND ITS SUBURBS.

We learn from the memorandum published by Dr. W. J. Simpson, the health officer of Calcutta, in connexion with the vital statistics of that city and its amalgamated area of suburbs, that the total number of births registered in Calcutta in September last was 693, giving an annual ratio of 17·8 per 1000 of population. The total deaths registered during the month were 1041, showing an annual ratio of 26·7 per 1000 The proportion of male to female deaths was as 158 to 100. The monthly total exceeds the corresponding figures of the past decade, and surpasses the decennial mean by 171. There were 82 deaths from cholera, against 29 in the preceding month. No deaths from small-pox. There were 124 deaths from bowel complaints, against 83 in the preceding month. From tetanus there were 80 deaths, against 64 in the preceding month; of these, 74 were under one year of age. The total mortality of infants under one year, reckoned on estimated births, was 342·9 per 1000 of population. In the amalgamated area of suburbs 326 births were registered during September, giving an annual ratio of 18·1 per 1000. The total number of deaths registered was 603, against 525 in the preceding month, giving an annual ratio of 33·6 per 1000. Of these deaths, 23 were from cholera, 270 from fevers, 89 from bowel complaints, and 56 from tetanus. In the tables of comparative mortality in cities of Bengal, Bombay, Madras, North-Western Provinces, and the Punjab having more than 50,000 inhabitants, we notice that in Madras, from Aug. 15th to Sept 11th, 1891, the annual death-rate amounted to 105·2 per 1000. At Cawnpore it was 55·2 for July, 49·5 for Delhi, 40·7 for Lahore, and 51·0 for Peswar for the week ending June 27th last. According to the latest return, that for the week ending Dec. 5th, 1891, the birth-rate at Calcutta was rather higher than the corresponding week of last year. There were 46 deaths from cholera, none from small-pox. The general annual death-rate was 39·7, against 32·4 per 1000, the mean of the last five years. In the amalgamated area of suburbs, the deaths (177) were lower during the week than in the corresponding week of the previous year: 21 deaths from cholera; none from small-pox. The death-rate of the week was 42·9 per 1000 of population. The general death-rate of the combined area is equal to 40·7 per 1000.

THE SERVICES.

PROMOTION IN THE INDIAN MEDICAL SERVICE.

The Times of India, of Jan. 16th, 1892, publishes the following:—"A question arose some time ago as to whether Brigade Surgeons of the Indian Medical Service could decline promotion to the rank of Deputy Surgeon-General. Medical officers holding lucrative civil appointments were disinclined to leave their posts when their turn came for military promotion, preferring to abandon their claim to higher rank. It has now been ruled that if, after considering all circumstances affecting any particular case, Government deem it expedient in the interests of the public service to nominate a Brigade Surgeon for promotion, that officer is not to be given the option of refusing it."

The death is reported of Brigade Surgeon S. P. White from pneumonia after influenza. He had retired in 1888, after twenty-eight years' service. The deceased was with the expedition against the Hazara tribes in 1868, during the Afghan War, the capture of Urzoo, and the engagements near Ghanzi.

Brigade Surgeon-Lieutenant-Colonel Samuel Maunsell died on Dec. 31st, 1891, at the West Indies. Lieutenant-Colonel Maunsell was a son of the late Rev. Thos. Maunsell, of Balnagarnon House, Fintona, County Tyrone.

Surgeon-Major Forbes Dick, M.D., Medical Staff, died on the 25th inst. at Queen-square, Lancaster, aged fifty. He became assistant-surgeon in the Army in September, 1863, surgeon in March, 1873, surgeon-major in April, 1876, and retired on half-pay in October, 1888

ARMY MEDICAL STAFF. — Surgeon-Major-General Sir James Arthur Hanbury, M.B, F.R.C.S.I., K.C.B., is placed on retired pay (dated Jan. 13th, 1892); Surgeon-Lieutenant-Colonel John Godfrey Rogers, M.B., D.S.O., retires on retired pay (dated Feb. 3rd, 1891).

NAVAL MEDICAL SERVICE. — The following appointments have been made at the Admiralty:—Surgeons: Graham E Kennedy to the *Defiance* (dated Feb. 13th, 1892); Jerome Barry, M D., to the *Ganges* (dated Feb. 16th, 1892); John Andrews, M.D., to the *Dart*, and Edward C. Cridland, M.B, to the *Paluma* (both dated Feb. 4th, 1892).

VOLUNTEER CORPS.—*Artillery:* 1st Forfarshire: William James Peddie, M.B., to be Surgeon-Lieutenant (dated Jan. 30th, 1892) — 1st Cumberland: Surgeon-Major J. A. Macdougall resigns his commission; also is permitted to retain his rank, and to continue to wear the uniform of the Corps on his retirement (dated Jan. 30th, 1892) —*Rifle:* 1st Surrey (South London): Charles Swaby Smith, Gent., to be Surgeon-Lieutenant (dated Jan. 9th, 1892) —3rd Volunteer Battalion, the Duke of Wellington's (West Riding Regiment): Richard Ernest Williamson, M.B., to be Surgeon-Lieutenant (dated Jan. 30th, 1892).—2nd Volunteer Battalion, the Duke of Cambridge's Own (Middlesex Regiment): Surgeon-Major C. A. Patten to be Surgeon-Lieutenant-Colonel (dated Jan. 30th, 1892) —2nd (South) Middlesex: Surgeon-Major T. Trent resigns his commission; also is permitted to retain his rank, and to continue to wear the uniform of the Corps on his retirement (dated Jan. 30th, 1892).

ROYAL INSTITUTION.—Professor E. Ray Lankester, F.R.S., will, on Thursday next, Feb. 11th, begin a course of three lectures on "Recent Biological Discoveries;" and the Right Hon. Lord Rayleigh, F.R.S., will, on Saturday, Feb. 13th, begin a course of six lectures on "Matter: in Rest and in Motion."

"Audi alteram partem."

THE ROYAL COLLEGE OF SURGEONS AND THE ASSOCIATION OF MEMBERS.

To the Editors of THE LANCET.

SIRS,—Your leader on the proceedings in the High Court of Law (Chancery Division) last week in the action Steele *v.* Savory, which ended so disastrously for the Association of Members, will have been seriously pondered over by all concerned. Many, no doubt, will be asking themselves, What next? What is the probable bearing of Mr. Justice Romer's decision on the Association and on the larger question bearing on the "abstract right to a share in the administration of the College"? Possibly the majority will think "sufficient for the day is the evil thereof." So be it; but there is just a point or two so far to which I should like to draw particular attention. First, it will appear to most of us that the validity or otherwise of By-law xvii. is scarcely worth further contention, certainly not in a court of law; as, come what may, there will be no further attempt to defy the Council on this question. That being so, there remains the larger contention, "the measure of the rights of the Members of the College," which has been the real bone of contention at the annual meetings since 1884. Now, it will scarcely be denied that this will be better met in the spirit you have foreshadowed, conciliation, and which will doubtless commend itself to all concerned, since, as you say, "it is a question upon which no court of law or of equity has jurisdiction to enter." This being so, the majority will see the advisability of at once acting upon so commendable a suggestion, "that both parties ..... resume the discussion with an enhanced desire to arrive at an agreement. [Most assuredly], if that could be effected, there seems to be no room for doubt that any settlement which might be adopted by consent would easily receive the necessary authorisation, and so acquire the force of law." May I, then, suggest that the Association of Members do forthwith appoint a deputation to wait upon the President and Council of the College, not simply to ascertain their views, but fully empowered to submit terms for the settlement of all matters in dispute? This course will, I believe, give the right turn to the discussion, tend to restore harmony between the Council and the Members, and put the final stop upon any further waste of money in useless litigation.

I remain, Sirs, yours truly,

ONE OF THE ASSOCIATION OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS.

Jan. 30th, 1892.

INFLUENZA.

To the Editors of THE LANCET.

SIRS,—Although the present epidemic shows signs of abatement so far as Stoke Newington and Hackney are concerned, I shall be glad if you will allow me a few remarks on the prevention and treatment of this troublesome scourge. For prevention the public seem to place most faith in ammoniated quinine, eucalyptus, tobacco, and whisky, the two latter especially commending themselves to many who are only too pleased to have some plausible excuse for indulging in their favourite weaknesses; but the fact that many victims of influenza were "protected" by one or all of these prophylactics is sufficient proof of their inefficacy. On the other hand, the suggestion of one of your correspondents some weeks ago as to the use of carbolic acid and glycerine in equal parts, a few drops to be placed on the handkerchief before leaving the bedroom each morning, is in my experience most valuable. I have largely recommended it, and so far as I know no one who has tried it has been affected. As regards treatment, the bicarbonate of potassium method seems to bear out much that Mr. Crerar contends for it; but in my opinion we have all the advantages, and none of the undoubtedly depressing disadvantages, of the bicarbonate in another drug, which is inexpensive (no slight consideration in practices where numerous club patients have to be provided with medicine), which alkalinises the blood but not the urine, which stimulates the cord and nervous system generally, and which is especially valuable in preventing, or when present mitigating, bronchitis and pneumonia, which as we all know are the complications from which we have most to fear. I refer to carbonate of ammonium. This drug in 5 gr. doses every four hours during the first stage I have largely used in the three outbreaks we have had, and patients declare that every dose gives relief to the pains. Besides this, if the case is seen at the outset I prescribe from 8 to 10 gr. of Dover's powder alone, or, in case of constipation, combined with from 2 to 3 gr. of calomel. In twenty-four to thirty-six hours the fever is subdued, the pains are relieved, the tongue cleans, appetite returns, and nux vomica rapidly restores the strength. For the troublesome but characteristic cough belladonna proves an efficient remedy. Salicylate of soda and antipyrin, or the new combination salipyrin, possess no advantages over carbonate of ammonium, and in some ways are distinctly its inferior.

I am, Sirs, yours faithfully,

WILLIAM WHITELAW, M. D.

Stoke Newington-road, N., Feb. 1st, 1892.

To the Editors of THE LANCET.

SIRS,—It may be worthy of remark, and in some measure may account for the great bound made in the apparent mortality from influenza in London during the past weeks, that a great difference is to be observed in the style of returning the death certificate by the certifying practitioner. At the commencement of an epidemic influenza is rarely returned as the primary cause, but is generally placed as a second or even third cause. During the further progress of the epidemic, when it has become much talked about, and, in a sense, fashionable, all this becomes reversed. We now find influenza returned as a primary cause, such complications as pneumonia and bronchitis being relegated to secondary positions. It even happens that chronic cases of diabetes, heart and kidney diseases, &c., are then returned as dying primarily of influenza; yet it must be obvious that these persons were, like ripe fruit, ready to fall from any disturbing cause, the influenza in these cases being but the proverbial "last straw." There is good reason for thinking, from the behaviour of influenza in previous epidemics, that we have reached the culminating point of the present epidemic, and may look for a period of decline. As most practitioners are finding themselves at present overworked, it may be some comfort to them to predict a period of general slackness during the ensuing summer months, such as was notoriously the case during the autumn months after the epidemic of 1891.

I am, Sirs, yours faithfully,

EDMUND GWYNN, M.D., M.O.H.

Vestry Hall, Hampstead, N.W., Feb. 1st, 1892.

To the Editors of THE LANCET.

SIRS,—I have just been reading in the daily press Dr. Parsons' very sensible suggestions with regard to the isolation and disinfection of cases of influenza, but I want to ask the question, Is it an infectious disease in the ordinary acceptation of the word? If yes, how is it we have none of it here at Monte Carlo, where all the means of spreading infectious disease are, so to speak, concentrated? Here in the Casino we have daily thousands of people from all quarters of the globe concentrated in a confined and artificially heated atmosphere; we have them all subjected to feelings of great excitement and great depression, the invariable accompaniments of gambling, and yet up to this date we have remained absolutely free from anything like an epidemic. I myself have seen only one case—a lady coming straight from America. She was taken ill on the journey, and I saw her immediately on her arrival. She was in a crowded hotel, and no precautions were taken. This was three weeks ago, and no other case has occurred in the hotel. A yacht came into the bay at Monaco, and I was asked to see a sailor on board who was ill. I found him suffering from well-marked influenza. This then ran through the whole crew. A strong wind sprung up, and the yacht had to be sent round to Villefranche (the Monaco bay not being a safe anchorage in stormy weather). The owner of the yacht then came on shore, and went to live in one of the largest hotels in the place. He also brought not a single germ of the disease to the other 200 people in the same hotel. I do not mean to assert for one moment that Monte Carlo will remain free from the epidemic for the

Digitized by Google

whole of this season, but I do most strongly feel that if it does come later on we must look to some other cause, atmospheric or otherwise, than infection in the ordinary acceptation of the word.

I am, Sirs, yours truly,
CHAS. F. HUTCHINSON, M.D.

Villa Mai, Monte Carlo, Jan. 27th, 1892.

To the Editors of THE LANCET.

SIRS,—I have treated during the last two years a very large number of cases of influenza, and have myself suffered from a severe attack of it. The more I have seen of the disease the more have I been convinced that there is no specific for it, and that there is no regular course of treatment suitable for any case. The disease manifests itself in a great variety of ways, and although it is undoubtedly of neurotic origin, yet the particular idiosyncrasy of the patient determines its variety: Antipyrin, phenacetin, salol, salicylate of soda, bicarbonate of potash, citrate of potash, and frequent drinking of abundance of hot water are all useful in cases suitable, but none of them can be styled "the best form of treatment." I have found that when the temperature was under 102° drinking plenteously of hot water, with a hot poultice over the kidneys, and frequent sponging of the limbs with hot water, was, with a warm bed and a comfortable room, a most satisfactory mode of treatment. I found in my own case the greatest relief from the sponging and the hot poultice over the loins. The disease is always of a most depressing character, and during convalescence is the time when the experience of the physician is most demanded, and where again it is impossible to lay down any fixed rule. Strychnine is the tonic most generally necessary; but here again particular symptoms must be considered. I think very great harm has resulted to the public from the advocacy of particular remedies, which have caused them to neglect the various details—generally the most essential thing to remember. The most important question is, When does the disease begin to be infectious and when does it cease to be so?

I am, Sirs, yours truly,
JOHN R. HAMILTON, M.D. &c.

Hawick, N.B., Feb. 2nd, 1892.

To the Editors of THE LANCET.

SIRS,—Like Dr. Gordon Black of Harrogate, I have had lots of cases of influenza accompanied by rashes simulating scarlatina and measles, but those cases occur mostly, I think, in the young. I have a boy patient just now who is suffering undoubtedly from an influenzal attack, where the measly rash is so general and pronounced on his body that my assistant persists in calling it a case of measles. I have also had a fatal case of influenza complicated by endocarditis, where the roseolar rash on the woman's breast, arms, and legs was very bright, and where the face, hands, and feet were much puffed and perfectly livid. This patient died suddenly on the third day of my attendance. Perhaps our locality may have something to do in the causation of exanthematous forms of this scourge.

I am, Sirs, yours faithfully,
A. ROSS PATERSON, M.D. Aberd., M.R.C.P. Ed.

Stockton-on-Tees, Feb. 1st, 1892.

A CASE OF UNRECOGNISED CERVICAL CARIES.

To the Editors of THE LANCET.

SIRS,—The case described by Mr. Owen, and published in THE LANCET of Jan. 30th, should call more attention to the diagnosis of caries of the spine in adults. I can bear witness to the fact that such cases are frequently left unrecognised. During the last few months I have had four cases of this kind. No. 1 was a young lady aged twenty-one, in whom symptoms of nerve irritation in the arms, and some pain in the upper dorsal region of the spine, occurred, regarding which there was a difference of opinion, but which has since developed into unmistakable inflammation of the vertebræ. No. 2 was a youth aged eighteen (hardly an adult, but beyond the age of childhood), in whom there was caries in the lower cervical and upper dorsal vertebræ, with considerable deformity, but in consequence of implication of the heart and liver the former disease was overlooked, at least as a cause of the symptoms, and the latter was considered to be the origin of the great pain and illness. The case was considered hopeless at first, but by careful treatment of the spine the symptoms have gradually lessened, and there seems a good prospect of ultimate recovery. No. 3, a lady aged forty, who had been quite well until thirteen months before I saw her, when pains began in the left arm, extending to the right arm and to the upper part of the dorsal region of the spine. Treatment for rheumatism and general health, including seaside air, had failed to relieve the constant pain, and the patient could hardly move from one room to another. There was projection from the seventh cervical vertebra to the third dorsal, and the surrounding part was swollen and painful upon pressure Suitable treatment relieved the pain, and after three months the patient has made considerable progress towards recovery. No. 4, a lady aged thirty-five, had had pain in the back of the neck for two years, with various symptoms of irritation of the cervical nerves, affecting the neck and arms. This case has been under treatment also nearly three months, pain ceasing almost entirely from the commencement of treatment, and the patient is gaining strength.

For the sake of brevity I have omitted details in describing these cases. With regard to treatment, I believe that mechanical fixation is the most important part. Recumbency in bed seldom, if ever, fixes the diseased parts perfectly. In recumbency alone, notwithstanding the use of sandbags, every movement of the body or the arms must disturb the diseased part, unless, indeed, the patient be fixed down tightly to the bedstead by the shoulders, the pelvis, and the abdomen. The latter proceeding would convert the bedstead into a splint, and it will be found that a carefully adapted mechanical apparatus controlling the spine and the head will be more supporting to the part, far less irksome to the patient, and more thoroughly adaptable by the surgeon to the requirements during the progress of the case.

I am, Sirs, yours faithfully,
Queen Anne-street, W., Feb. 1st, 1892. NOBLE SMITH.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

The Notification of Measles in Newcastle.

AT a special meeting of the Corporation of the Newcastle Sanitary Committee, held last week, to take into consideration the notification of measles, a long and interesting discussion took place, and ultimately a vote was taken, the numbers for and against the notification of measles being equal. The chairman, however, declined to give his casting vote, in order that the matter might stand over for a short time for reconsideration. It is well known that our city officer of health holds strong views, which he has frequently expressed, as to the notification of this disease, which, he thinks, causes more loss of life than scarlet fever. I believe that the notification of measles will be conceded in a short time. At present the influenza is the all-absorbing topic of conversation; the public appear to be unable to think of more than one disease at a time, and whichever is foremost in their minds obscures all others. The notification of influenza was mooted the other night at the meeting of our Clinical Society, but the medical officer of health thought that as isolation was impracticable notification would be useless. Certainly the stage of incubation being for the most part so brief, it is not easy to see what good could accrue from notification, and it is well to avoid putting more burdens on our already patient profession.

Newcastle Lying-in Hospital.

The annual meeting of the governors of the Newcastle Lying-in Hospital was held last week. The report stated that 247 cases had been attended during the past year, and two deaths had occurred in the out-door department of the charity. The treasurer's statement showed a balance of £30, so that the hospital is now free from debt.

Carlisle.

It was mentioned at the board of guardians that influenza was somewhat abating, that the old people had been very severely attacked, and some of the cases were very bad ones. On one day last week there were 110 cases. The medical officer, in his annual report, states that scarlet

Digitized by Google

fever had been very prevalent during the year, 564 cases having been notified; but the death rate for the year had not been more than 19 per 1000, allowing for some cases not belonging to the Carlisle urban sanitary district.

Criminal Law.

In the course of a lecture lately delivered at Carlisle by Dr. Lediard, he referred to the post-mortem examination of the dead, which, he said, should be watched in the prisoner's interests, apart from the prosecution. The various steps of dealing with the body or parts of the body should be watched in the prisoner's behalf. The organs as removed from the body should be noted and observed by a medical man engaged for the prisoner. The eye sees what it expects to see. A medical man was looking out for certain appearances, and his judgment might mislead him. Where money was at hand they found that prisoners' interests were invariably guarded in the manner described, and fallacies of observation and errors of judgment corrected at once with the happiest results. Dr. Lediard thought that a Court of Criminal Appeal should be as easy of access to the poor as the rich. Upon the whole, he favours the Scotch system in criminal procedure, where the procurator fiscal takes action, instead of, as with us on this side of the Border, the police.

High Rate of Mortality at Annan.

At the border town of Annan the death-rate for the last month has risen to the high figure of 70 per 1000 per annum. Old persons have died in great numbers.

Workington Infirmary.

The annual report of the Workington Infirmary has been issued, and it shows that ninety-three patients, principally surgical cases and operations, had been treated during the year. The financial position of the infirmary was good, as it closed with a balance in hand of nearly £200. One very satisfactory feature was the workmen's subscriptions, which reached the large sum of over £600.

Health of Ripon.

At a meeting of the Ripon Corporation Sanitary Committee the medical officer of health, Mr. C. Husband, presented his report, which showed that the death-rate for the whole city in 1891 was 20·5 per 1000, and, excluding public institutions, 18·3. Of the total deaths, 16 were of persons not belonging to Ripon, which reduced the death-rate for residents to 17·1. There had been ten deaths from zymotic diseases.

The Malton Medical Officership.

The local papers state that there has been some hitch or mistake in the election of a medical officer for the Malton district, and voluminous correspondence with the Local Government Board has resulted. Some say that a medical officer has been elected, and others say the contrary. It appears that there has been some mistake with the voting cards of the guardians, and probably a new election will take place.

Newcastle-upon-Tyne, Feb. 3rd.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Longmore Hospital for Incurables, Edinburgh.

THE annual meeting of the managers of this institution was held last week, Lord Provost Russell presiding. The report stated that on Dec. 31st, 1890, there were sixty-seven patients in the hospital, and there were admitted during the past year twenty-three, making a total of ninety. Of these, seventeen males and fifteen females died, and four left of their own accord, leaving in the hospital on Dec. 31st last a total of fifty-four. It has been mentioned on several previous occasions that the managers were anxious to increase the accommodation for patients, as they had many more applications for admission than they could provide accommodation for. This report intimates that the necessary building is under course of erection. The old east wing has been pulled down and a new and more suitable wing is being built which will provide accommodation for thirty-four additional patients. Owing to the pulling down of part of the old structure the number of patients had, of course, to be temporarily reduced. When the alterations are completed there will be accommodation for about 100 patients. This will necessarily involve a greater annual outlay, and it is disappointing to note that the public are not subscribing as liberally to the institution as it deserves.

Edinburgh Dental Hospital.

The annual meeting of the directors and contributors to this hospital was held last week, the Lord Provost occupying the chair. From the report it appears that during the year 8617 cases had been treated. The addition of a mechanical department has been of great benefit to the recipients. The report expressed regret that, owing to the proposed extension of the Royal Infirmary, the Dental Hospital would cease to occupy its present premises, which occupied part of the ground included in the proposed extension.

Edinburgh Eye, Ear, and Throat Infirmary.

The institution which bears this name is a dispensary with a few beds attached to it. Its annual meeting was held last week, and from the report it appears that the number of patients in each department has slightly increased, and that the institution continues to do useful work.

The Edinburgh Diseased Meat Case.

The butcher who, as intimated last week, was fined for selling the carcase of a bullock which had died of anthrax has been further fined £20 by the county authorities for not intimating the case to them. This case, and the fact that much meat unfit for food is seized in the city, have caused a small public scare, and people begin to wonder what is safe to eat or to drink.

The Health of Edinburgh.

The mortality last week was 104, and the death-rate 20 per 1000. Diseases of the chest accounted for 50 deaths, and zymotic diseases for 7. The intimations for the week were: Typhoid fever 4, diphtheria 3, scarlatina 18, and measles 50.

General Council of the University of Edinburgh.

A special meeting of this body has been summoned for Friday, chiefly to consider amendments upon some of the later draft ordinances of the Universities Commission.

Feb. 2nd.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Royal College of Surgeons in Ireland: Schools of Surgery.

THE new buildings—anatomical, physiological, and chemical departments—which have been erected at a cost of some £5000, were formally opened on Monday by Mr. H. Gray Croly, president of the College. The dissecting-room is 74 ft. long by 64 ft. wide and 22 ft. high, lighted by a glass roof, and by electric lamps after sunset, while the chemical laboratory is 64 ft. long by 28 ft. wide, above it being the lecture theatre, all being fitted with the electric light. Mr. Croly made some brief remarks on the new buildings, and then said he had one more duty to perform, and that was to confer the honorary public health diploma on one of their most distinguished professors, Sir Charles Cameron, who was known to them not only as one of their professors of chemistry, but also as having been a past president of the College, a diplomate in Public Health, Cambridge University, and was three times re-elected President of the British Public Health Medical Association. Sir C. Cameron, in returning thanks, remarked that it was a source of great satisfaction to him to find that the study of public health was now regarded of so much importance that public medical officers of health were found in all the principal towns in our own countries, as well as all over Europe, and that it was deemed sufficiently worthy to be made the subject of a special diploma, sharing that honour with medicine, surgery, and obstetrics.

National Hospital for Consumption.

A public meeting in support of the proposal to erect a hospital for consumption near Dublin will be held on the 17th inst. at the Royal College of Physicians. Among those who have promised to attend is Her Excellency the Countess of Zetland. The movement has largely engaged

Digitized by Google

public sympathy, and considerable support may confidently be expected in aid of the necessary funds for erecting and endowing an institution of the kind proposed.

Tercentenary of Trinity College.

The Trinity College Dramatic Committee have selected "The Rivals," by Sheridan, as the play to be performed by the students of the University during the tercentenary celebration.

The Ulster Hospital for Women and Children.

At this hospital the number of cases treated in the wards and the extern departments shows marked progress. A large number of operations were performed, with only three deaths during the year. The building in Fisherwick-place not being satisfactory, the present premises in Mountpottinger were secured. A bazaar is to be held next autumn, the proceeds being for the building fund and ordinary expenses. The hospital is now in every respect fully equipped. A resolution was adopted expressing sympathy with Professor Dill in his illness.

The Samaritan Hospital for Women, Belfast.

During 1890 there were 86 intern and 775 extern patients; in 1891 there were 56 intern and 479 extern patients. By far the greater number of those admitted were surgical cases. During the past few years the training of lady nurses has been undertaken with satisfactory results. There has never been a death from chloroform, although it has, since the foundation of the hospital in 1872, been given in over three thousand cases of operations. There is an increase in the number, and of nearly 50 per cent. in amount, of the public subscriptions for 1891 as compared with 1890, but there has been a decrease of £200 in the receipts from patients, which in previous years was the principal source of income. The late Miss Charters has bequeathed £1000 to the funds.

The Hospital for Sick Children, Belfast.

During the year 1891 there were 347 intern and 7592 extern patients. During the present session forty senior students are attending the clinics at the hospital, which is the largest class held in the institution since its foundation, and this fact indicates the important position which the institution occupies in the Belfast Medical School. The income for the year amounted to £966 4*s.* 9*d.*, and the expenditure to £1010 3*s.*

Belfast Lying-in Hospital.

At the annual meeting, held on Feb. 2nd, I find from the report presented that the number of intern patients (211) has been greater than in any previous year, while 165 were attended at their own homes. The hospital is in good working order. The dispensary, which is open thrice weekly, has been taken advantage of by 1480 women and children. Arrangement has been made for the admission of lady pupils. During the past year ten nurses were trained.

Influenza.

The epidemic of influenza, which for a long time was so prevalent in Belfast, may now be said to have disappeared, there being only a few isolated cases.

The death is reported of John Simpson Jackson, M.B., L.R.C.S.I., surgeon, ss. *Angola*, who was washed overboard in a gale recently. Great sympathy is felt for his father, Sir Robert Jackson, C.B., of Eglinton, Sandimount, near Dublin, a retired Deputy Surgeon-General.

Dr. John Armstrong, Government medical officer, died recently at Dominica, West Indies.

Feb. 3rd.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

KI or NaI? The Prevention of Iodism.

THERE can be no question that the most efficient of all iodine compounds is the potassium salt. Its supremacy in the treatment of tertiary syphilis is undisputed, and in the remedying of the divers symptoms due to arterio sclerosis no agent gives such satisfactory results. Unfortunately, many patients are intolerant of this drug, and uncomfortable or even grave symptoms of iodism too often render its employment impossible. Nor can it be denied that, with the modern school of practitioners, theoretical considerations, based upon the knowledge gathered in the physiological laboratory that the salts of potassium act as protoplasmic poisons, militate against the administration of a drug which has rendered such good service in the treatment of degenerative processes. One cannot but suspect that such considerations, much less than clinical ones, have induced M. Huchard to prefer, for the last few years, the sodium to the potassium salt. At a meeting of the Société de Thérapeutique held on Jan. 27th, M. Constantin Paul asked M. Huchard if his enthusiasm for the sodium salt had not, as appeared from his recent utterances, somewhat cooled down. M. Paul himself expressed his decided preference for the potassium salt, deeming it to be vastly superior to its sodium congener. The discussion that followed showed that there was a general consensus of opinion as to the inefficacy of sodium iodide in syphilis, and elicited further from M. Huchard the confession that his views were veering round in favour of our old ally the potassium salt. His chief objection to it was its occasional irritating action on the renal filter. The sodium salt was free from this objection, but must be used in much larger doses to produce equivalent results. He believes that in such diseases as angina pectoris and myocarditis, general arterio-sclerosis is present, and consequently renal insufficiency, which the employment of the irritating potassium salt would aggravate. In conformity with the precept formulated originally, I believe, by Sir James Paget, and since endorsed by all English authorities—viz., to prescribe KI associated with some free NH_3,—I have always done so, but without always succeeding in averting iodism. In one syphilitic patient of mine the very first dose of five or ten grains thus prescribed invariably produced coryza, frontal headache, and sometimes a crop of acne. It has, however, never been my lot to witness such a serious form of iodism as œdema of the glottis, although such a *contretemps* has been not unfrequently noted. Quite recently Dr. Kessler of Dorpat recorded such an accident in the person of a woman, into whose vagina he had poured a teaspoonful of a one-third glycerine solution of potassium iodide. It is taught in the Paris school that iodism is more readily induced by small than by large doses. Two German physicians, Drs. Röhmann and Malachowski of Breslau, have been lately experimenting with bicarbonate of sodium as an antidote for iodism, believing that the ingestion of this salt, by rendering the blood alkaline, prevents the decomposition of potassium iodide and the consequent liberation of iodine in the free state. Two years' experience has convinced them that in bicarbonate of sodium, given synchronously, in two daily doses of forty or fifty grains, with potassium iodide, an agent has been discovered capable of counteracting, or even altogether preventing, the development of toxic symptoms.

Then and Now.

Professor Charcot is probably the most renowned teacher of which this Faculty can at present boast, hardly a foreigner visiting the Paris hospitals failing to make the classical pilgrimage to the Salpêtrière, where the learned and popular neurologist exercises sway. It may consequently interest the medical world to learn that at least one of M. Charcot's (probable) ancestors was an adept in the practice of *suggestion*, only the subjects whom he influenced were not hysterical girls, but—wild cats! The *modus operandi* also differed considerably, as will be perceived, from that now in vogue in the wards of the Salpêtrière. The following passage, which is extracted from Boguet's work entitled "Discours des Sorciers," third edition, Lyon, 1610, I transcribe without modernising the racy old French in which it was written. The *Progrès Médical* states that M. Charcot has still some relatives living in the same Gex district (now included in the Department of the Ain) mentioned in the extract: "Le semblable advint environ quarante ans lorsque les Bernois tenoient le Bailliage de Gex, en la personne d'un Charcot, homme de la mesme Terre et qui estoit de la religion prétendue réformée; celuy-cy fut assailly de nuict au bois de Rats, par une multitude de chats, à l'encontre desquels il se mit en défense, se servant d'une espée qu'il portoit, mais cõme il recogneut que son espée ne luy profitoit en rien, il fit le signe de la Croix, et lors tous les chats disparurẽt. Le Bailly nommé Augustin de Lutherno Bernois, ayant esté adverty du faict, mande Charcot qui luy confirma la chose en la sorte qu'elle a esté rapportée, et lors le Bailly luy dit, que s'il recognoissoit que le signe de la Croix luy

Digitized by Google

fut profitable, il s'en deust tousiours aider à l'advenir. Je tiens l'histoire du sieur de Pougny, Gentilhomme de la terre de Gex et personnage d'honneur."

Insanity in Paris.

From a report just issued by Dr. Paul Garnier, physician to the special infirmary attached to the Préfecture de Police, it appears that insanity has increased in notable proportions (30 per cent.) in this city during the period included between 1872 and 1888. In the former year there were, in fact, registered at the Prefecture 3080 cases, as against 4449 in 1888, the grand total for that period of sixteen years being 62,572, including 34,882 males and 27,770 females.

Street Demonstrations by Medical Students.

Great dissatisfaction has been aroused in student circles by a recent announcement, to the effect that, in order to reconcile the terms of medical studies with those of the new military law, the limit of age at which the post of interne or house surgeon or physician can be competed for would henceforth be fixed at twenty-five. Numerous petitions have already been addressed to the authorities, with a view of having the obnoxious regulation amended. Feeling runs high on the subject. On Wednesday, the 27th ult., several hundred medical students repaired in groups to the headquarters of the Assistance Publique in the Avenue Victoria, and noisily protested against the measure. Dr. Peyron, the director, succeeded in calming the tumult by assuring his young friends that the matter was to be reconsidered, and that, in arriving at a final decision, their true interests would be kept in mind. Both the *Progrès Médical* and the *Bulletin Médical* appeal to the body of students to maintain a dignified and calm attitude, and to refrain from compromising the success of their agitation by holding disorderly street demonstrations.

Paris, Feb. 3rd.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Street Hygiene.

AT a recent meeting of the German Public Health Society Dr. Theodor Weyl spoke on the street hygiene of Paris and London, and recommended the adoption in Berlin of many of the arrangements in vogue at those places. The gist of his remarks was as follows: Wooden pavement has been in use in London and Paris for many years past, and has proved a great success, even in the most frequented streets. The fact that it has been less successful in Berlin may be due to faults of construction and treatment. In Paris and London there are no rails in streets paved with wood. The pavement is copiously watered. Drains and pipes are not laid under it, but under the side walks. The main thing, however, is good construction. In London and Paris sweeping is always preceded by watering, which is not the case here, to the serious detriment of the public health. The public closets in Paris are not worthy of imitation, because hygienic considerations are to a large extent subordinated to advertising purposes, but those of London are exemplary. The depositing of rubbish within or even in the immediate vicinity of cities is altogether to be condemned. The removal of snow costs Berlin about £19,000 a year, because it is not thrown into the river or sewers as in London and Paris, but carted out of the city. In conclusion, Dr. Weyl warmly recommended the London plan of regulating traffic by placing the lamp-posts in the middle of the street.

Dangerous Stoves.

The President of Police in Berlin has repeatedly warned the public against the use of certain forms of stoves. The President states that one case of poisoning by carbonic oxide occurred in Berlin and two in Wiesbaden in the winter of 1887-88, owing to the use of such stoves. It has been proved by experiments in the Hygienic Institute here that such stoves are dangerous.

Influenza.

The number of deaths in Berlin from influenza from the beginning of the present epidemic till the 16th ult. was 492. Of the fifteen normal schools of the kingdom of Saxony, twelve are closed, owing to the epidemic.

Statistics.

The number of marriages in Berlin in the week which ended on the 16th ult. was 157. The number of children born alive was 974, of whom 104 were illegitimate; 24 were born dead, of whom 5 were illegitimate. The number of deaths reported was 680—1 from typhus fever, 1 from quinsy, 3 from roseola, 3 from syphilis, 7 from whooping cough, 7 from gastro intestinal catarrh, 9 from measles, 11 from scarlet fever, 14 from diarrhœa, 14 from diarrhœa with vomiting, 18 from cerebral apoplexy, 21 from diphtheria, 28 from senile decrepitude, 32 from influenza, 63 from pneumonia, and 100 from phthisis. Seven persons died violent deaths, 3 of whom were hanged, 3 shot, and 1 driven over. Six of these deaths were suicides. The death-rates of the chief German cities were as follows: Krefeld, 9·9; Düsseldorf, 16·5; Stuttgart, 16·9; Strasburg, 17·2; Frankfort, 18·5; Leipsic, 18·7; Elberfeld, 19·8; Hanover, 20·7; Bremen, 21·1; Barmen, 21·2; Stettin, 21·4; Dantzic, 21·7; Berlin, 21·8; Breslau, 25·4; Dresden, 25·6; Königsberg, 25·8; Aix-la-Chapelle, 26·5; Nuremberg, 26·5; Hamburg, 26·6; Altona, 27·6; Magdeburg, 28·7; Munich, 30·4; Cologne, 31·7; Chemnitz, 33·8.

Berlin, Feb. 2nd.

Obituary.

ALFRED CARPENTER, M.D.LOND., M.R.C.P.LOND., J.P., &C.

FOR the last forty years the name of Dr. Carpenter has been at once familiar to and respected by all who have been interested in the progress of sanitary matters during the past half-century. Himself the son of a medical man, his general and medical education received marked attention, and his career as a student of St. Thomas's Hospital, when it was in less pretentious quarters than at present, is one which will compare with the most outstanding in the profession. He took several qualifications, ultimately becoming M.D. of London. His work was one of reform, and extended into many fields of labour. Early closing, sanitary progress, public baths, establishment of sewage farms, house drainage, and adulteration of food were subjects on which he spoke and wrote with unfaltering voice and unflinching pen. Every movement for the advancement of science and literature found in him a warm supporter. His writings embrace almost every sphere of sanitary work. He was a member of the Health Committee of the Social Science Association for many years, and its transactions testify to the work he performed. As a member of the Sanitary Institute he materially assisted the end in view. The motive power of his action was the belief so frequently expressed that the establishment of healthy homes for working people was the only true solution of the main problem in sanitary science. "You put the poor creatures in such conditions that their health has been failing for months, and when they die you blame the drainage." Dr. Carpenter would have heartily endorsed every syllable of this truth. His Glasgow paper, read in St. Andrew's Hall, entitled "Public Health: a Working Man's Question," was founded upon that text. It would have been marvellous beyond question if the ideas of a man possessed of his qualities of origination had not clashed frequently and rudely with certain interests. He did not escape calumny. No man of action ever does. So great was the friction engendered, on the only occasion on which he sought political honours, that he was set upon and roughly handled, and "eventually ducked in a pond." He suffered for his principles in good company. The roll of such is not too long, but every name on it is stereotyped for ever, for good, and posterity will read and think, and the verdict will be different. He was a magistrate for Croydon. In that capacity he betrayed a remarkable belief in the ancient theory of "sparing the rod and hating the juvenile offender." His invariable remedy for this class of delinquent was "a sound whipping." Had he survived he would have been elected to the post of chief magistrate. Years ago this honour was offered to him, but his many other public duties prevented his acceptance of the post. He was a vice-president of the British Medical Association, having been president of its council from 1879-81.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on Jan. 28th the degrees of B M. and B S. were conferred on the following:—

George Tolcher Eccles, Downing.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The following gentlemen, having conformed to the by-laws and regulations and passed the required examinations, were at a meeting of the College on Jan. 28th admitted Licentiates:—

Adams, Alfred, St. Barthol.
Adams, E. Weaver, King's Coll.
Adams, W. Francis, King's Coll.
*Archer, Stafford L., St. Barthol.
Armstead, Hugh W., St. Barthol.
Allee, John, St. Barthol.
Barker, Chesman, St. Barthol. & Sheffield.
Bell, Jas. Adamson, King's Coll.
Biddle, Henry George, Guy's.
Billson, Charles, St. Thomas's.
Bishop, George T., Charing-cross.
Blackwell, A. S., St. Barthol.
Bolus, Harry Boulcott, Guy's.
Braithwaite, Charles B., Guy's.
Browne, John James, Guy's.
Brownlow, Harry L., St. Barthol.
Burden, Henry, St. Thomas's.
Cooke, William H., St. George's.
Cooper, Arthur T., Univ. Coll.
Day, Joseph H., Charing-cross.
*Dolamore, W. Henry, St Mary's.
Dorman, M. R. P., St. Thomas's.
Drake, W. Elliot, St. Thomas's.
*Eccles, R. Burton, St. Thomas's.
Ellis, Fred, London.
English, Thos. Harks, London.
Evans, John, Liverpool.
Everett, Ernest W, St. Barthol.
Fearnley, Jonathan, Leeds.
Fennings, Arthur Allen, St. Mary's & Durham.
Finley, Harry, Univ. Coll.
*Fraser, Reginald Conrad. Guy's.
Freeland, Douglas L., Middlesex.
Glover, Lewis G., St. Barthol.
Graham, Charles H., St. Barthol.
Green, Joseph, Manchester.
*Greenhalgh, Arthur, Manchester.
Griffiths, G. Batho, St. Barthol.
Haslam, William Arthur, Guy's.
Haydon, Arthur Geo, St. Barthol.
Hayes, William A., Univ. Coll.
Higgs, Walter Alpheus, Guy's.
Hignett, Lionel W., Edinburgh.
Hopkin, Richard, London.
Hutton, James William, Leeds.
Iliewicz, Edmund M., St. Mary's.
Jerome, George P., Birmingham.
Jones, L. Gwynn D., Manchester.
Jones, Wm. Black, St. Barthol.
Kendall, Herbert W., Middlesex.
Kitching, Charles A., London.
Lacey, Allan Ramsey, Guy's.
Lee, Sidney Herbert, Middlesex.
*Leicester, Thomas, St. Thomas's.
Lemarchand, A. W., St. Barthol.
Lewarne, Frank, St. Barthol.
Lewis, Herbert W., Westminster.
Lister, Septimus R., St. Barthol.
Lloyd, Fredk. Geo., St. Barthol.
Lord, Percy, Guy's.
Lumley, Fredk. Davidson, Guy's.
Lunn, Cyril R., Birmingham.
*McAnally, Arch. A., King's Coll.
McKinnon, Arch. A., King's Coll.
McMichael, A. W., Birmingham.
Marin, F. Baptiste, Westminster.
*Martland, Thomas, Manchester.
Mathews, Wm. Robert, London.
Miller, John, St. Barthol.
Minshall, Arthur G., Univ. Coll.
Morgan, Harry de R., St. George's.
Morrison, James, St. Barthol.
*Nash, Charles, King's Coll.
Newby, Gervase E., Univ. Coll.
Nicholls, Sydney R., London.
Norman, George, Westminster.
Norris, Arthur Ernest, Guy's.
Nuttall, Walter W., St. Barthol.
Passmore, J. E. Sanders, London.
Pauling, W. T., St. Thomas's.
Phillips, Percy C., St. Thomas's.
Pickford, James S., Manchester.
Pitt, Tom, Bristol.
Porter, Frank C., Charing-cross.
Powrie, Percy C., Univ. Coll,
Prall, Cedric B., St. Thomas's.
*Prosser-Evans, J., Univ. Coll.
Prynne, Harold V., Middlesex.
Ralph, C. H. Danson, Guy's.
Ramsay, George, King's Coll.
*Richardson, W. J., King's Coll.
Roth, Walter E., St. Thomas's.
Rowell, John George, Leeds.
Rutter, F. Burchett, London.
Sargent, Hugh Cann, London.
Senior, Harold D., Charing-cross.
Star, P. Hobling Mills, Bristol.
Steegmann, E. John, St. Mary's.
Thomas, Henry, St. Barthol.
Thomas, William, London.
Thorne, Berthold Bezly Thorne, St Barthol.
Turner, Joseph G., St. Thomas's.
Turner, Olivier Polhill, Univ. Coll.
Visick, C. H. Clarence, Univ. Coll.
Voisin, E. O. Bishop, Univ. Coll.
Wallace, F. Gore, St. Thomas's.
Warner, Thomas, King's Coll.
Waters, H. Geo., St. Thomas's.
Watkins, D. J. G., St. Barthol.
Weichert, Charles J., Univ. Coll.
Whiteford, Chas. H., St. Barthol.
Whitehead, A. Longley, Leeds.
Wiglesworth, T. Ridler, Bristol.
Wild, Henry Sydney, St. George's.
Wilkinson, Harry Bacon, Guy's.
Williamson, J. H., Manchester.
Wood, Cyril Geo. Russ, Bristol.
Worthington, Harry E., Guy's.
Wrench, Edward Branson, Cambridge & St. Thomas's.
Wylie, J. T. Roy, St. George's.

* Candidates who have not presented themselves under the Regulations of the Examining Board.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS IN IRELAND: CONJOINT SCHEME.—The following candidates have passed the Final Examination:—

E. H. Beaman, H. Bouchier-Hayes T. F. Dillon, J. J. M. Dowzer, J. B. Elmes, M. Ferguson, F. W. Foott, E. F. Frazer, W. C. Hamilton, M. Keay, H. B. Ludlow, E. W. Lynch, J. M. Mangan, R. Moynahan, A. W. Power, G. H. Russell, I. G. Warren, R. J. White, G. T. Whyte, D. E. Williams.

The following have passed in the subjects indicated:—

Medicine.—M. J. Chevers, D. H. Foley, P. J. Garland, F. A. Madden, A. R. Moore, W. W. Scarlett, S. W. Wilson, Jane Wynne.
Surgery.—H. W. Cave, M. J. Chevers, C. E. Cowen, D H. Foley, P. J. Garland, F. J. Greeves, A. R. Moore, W. W. Scarlett, Temple Smyth, Frederick O. Stoker.
Midwifery.—I. Crumley, F. L. Flood, F. J. Greeves.

BRITISH MEDICAL SERVICE.—The following is the list of Surgeons on probation of the Medical Staff of the British Army who were successful at both the recent London and Netley examinations. The prizes are awarded for marks gained in the special subjects taught at the Army Medical School. The final positions of these gentlemen are determined by the marks gained in London added to those gained at Netley, and the combined numbers are accordingly shown in the list which follows:—

	Combined Marks.		Combined Marks.
*Pilcher, E. M. ..	6094	Mitchell, L. A. ..	4549
Johnson, H. P. ..	5121	Fleming, C. C. ..	4533
Beyts, W. G. ..	5219	Hennessy, J.	4546
Stalkartt, H. A. ..	4833	Martin, C. B.	4501
Dunn, H. N.	4832	Buchanan, G. J. ..	4395
Withers, S. H. ..	4794	Lawson, C. B. ..	4366
Morphew, E. M. ..	4744	Hughes, G. R ..	4314
Anderson, E. C. ..	4648	Kelly, J. F. M. ..	4337
Tyacke, N.	4619	Crawford, G. S. ..	4286
Holt, R. H. E. G. ..	4562	Alexander, J. D. ..	4260

* Gained the Montefiore second prize.

INDIAN MEDICAL SERVICE.—The following Surgeons on probation were successful at both the recent London and Netley examinations:—

	Combined Marks.		Combined Marks.
Seton, B. G.	6079	Mitter, R. K.	5589
*Sprague, W. C. ..	6044	Armstrong, W. E. A.	5507
†Elliot, R. H.	6027	Yeates, R. A.	5456

* Gained the Martin Memorial Gold Medal with the De Chaumont prize in Hygiene, the prize in Pathology presented by the Director-General of the Army Medical Department, Sir William Mackinnon, K.C.B., and the Herbert prize of £20.
† Gained the Montefiore Medal and prize of 20 guineas, and the prize in Clinical Medicine presented by Surgeon-General W. C. Maclean, C.B.

CREMATION.—In view of the increase in the practice of cremation, the directors of the General Cemetery Company have decided to build within the monumental chambers at Kensal-green a columbarium or receptacle for cinerary urns.

THE GERMAN HOSPITAL, DALSTON.—The annual report just circulated shows that the number of in-patients admitted during the past year was 1536, of which 303 were cases of accident. In the same period, 364 patients were received into the convalescent home. The total number of out-patients treated at the hospital, and the Eastern and Western Dispensaries, was 24,757. The financial statement shows a balance of £278 for the general fund. Another ward for women was much needed.

PROPOSED NEW COUNTY ASYLUM FOR LANCASHIRE. At the meeting of the Lancashire Asylums Board at Preston on the 28th ult. it was reported that the present asylums were crowded, and that the normal increase of lunatics in Lancashire was 200 per annum. It was resolved to recommend to the County Council the erection of an institution for the reception of harmless incurable lunatics and imbeciles combined, with a school for juvenile imbeciles under separate superintendence and on the same estate.

MANCHESTER MEDICO-ETHICAL ASSOCIATION.—The following gentlemen have been elected by the Committee for election as office-bearers and committee for the year 1892 President: Dr. Henry Ashby. Vice-Presidents: Drs. Alfred Godson, Simeon Holgate Owen, William Japp Sinclair, and Mr. John Broadbent. Treasurer: Dr. Lloyd Roberts. Secretaries: Dr. Frederick H. Collins, and Mr. John Ferguson. Committee: Drs. Hugh Walter Boddy, Henry A. G. Brooke, Thomas Harris, James Holmes, John Fisher Le Page, William Milligan, Seigmund Moritz, Robert A. Murray, and Charles Gordon Lennox Skinner; Messrs. Joseph Foster, Herbert Lund, and John Antoine Palanque.

IPSWICH BOARD OF GUARDIANS.—At the meeting of the board at the Town Hall on the 29th ult. the following report of the Out-Relief Committee was presented, and ultimately adopted:—"Your committee, having fully considered the question of medical relief, recommend:—1. That there should be one medical officer instead of three. 2. That Mr. Edwards should be paid a retiring pension of £60 a year. 3. That Mr. Adams should be paid a similar pension of £50. 4. That the medical officer should attend at the out-relief station every morning at 10, for the purpose of seeing patients. 5. That the medical officer should employ a deputy, equally qualified with himself. 6. That the deputy be allowed to see chronic cases, and otherwise assist the medical officer in the discharge of his duties. 7. That the guardians should contract with a druggist for the supply of all drugs, at their expense. 8. That the druggist supplying the drugs should send a dispenser to attend at the out-relief office morning and evening to make up the medical officer's prescriptions. 9. That the medical officer should be paid £280 a year, rising £10 a year to £320."

Digitized by Google

SIR P. DUN'S HOSPITAL, DUBLIN.—This institution has received, in response to the special appeal for funds, a cheque for £200 from Lord Iveagh, and £100 each from Sir E. Hudson Kinahan, Bart., and Mr. John Jameson.

FOLKESTONE.—Dr. Ross, of Christ Church-road, Folkestone, has been unanimously chosen a member of the Library and Museum Committee, in the place of Mr. Saunderson, deceased.

HERTFORD GENERAL HOSPITAL.—The annual report for the year 1891 shows an increase in the number both in- and out-patients. There was a decrease in the year's receipts (chiefly arising from the falling off of donations and legacies) amounting to £387 3*s.* 9*d.*

WELLINGTON COLLEGE.—A special meeting of the governors of Wellington College was held yesterday, at the Fine Arts Commission Room, Palace of Westminster. The governors present were—Colonel Talbot (vice-president), his Royal Highness the Duke of Connaught, his Royal Highness Prince Christian, the Duke of Wellington, the Bishop of Rochester, Sir George Russell, Sir Lintorn Simmons, Sir Dighton Probyn, Sir George Harman, Mr. Walter, and Mr. J. F. Chance (Secretary).

THE PREVENTION OF CRUELTY TO CHILDREN.—During the quarter ended Dec. 31st, 1891, the National Society for the Prevention of Cruelty to Children investigated 1974 complaints of cruelty, affecting the welfare of 4662 children. In 1168 cases warnings were given to the offenders; in 280 cases the offences were of so gross a nature as to necessitate prosecution (convicted 265, discharged 15); and the rest were otherwise dealt with. Fifty-four years of imprisonment and £51 in fines were inflicted.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY. The following gentlemen have been elected office-bearers for 1892:—President: John Woodman, M.D., F.R.C.S. Vice-President: James Somer, M.R.C.S. Treasurer: J. D. Harris, M.R.C.S. Council: E. J. Domville, M.R.C.S., J. Mortimer, M.B., C. E. Bell, M.R.C.S., C. H. Wade, M.A., M.R.C.S., W. Langran, L.R.C.P.E., and A. Curtis, L.R.C.P.L. Auditors: A. C. Roper, F.R.C.S.E., and J. M. Ackland, M.R.C.S. Secretary: A. G. Blomfield, M.D.

TORBAY HOSPITAL AND DISPENSARY.—This charity maintains its utility, and continues to extend its benevolent work. The cash account again shows a deficiency, and the board had resolved to apply to current expenses the amounts in hand received for life governorships to reduce the overdraft. The executors of the late Miss Lavinia Warrington have offered to bestow £7000 for the purpose of improving and enlarging the hospital, which the governors have long contemplated. This generous offer has been accepted. A ward will be named after the donor.

FOOTBALL CASUALTIES.—On the 26th ult. a young man sustained a fracture of the leg while playing in a match between the Cardiff Police and Corporation Officials. He was taken to the infirmary and detained.—On Saturday, in a match between Heywood and Heywood Central Clubs, a player was kicked on the left knee, and on medical assistance being obtained it was found he had sustained a serious fracture of the "knee-cap."—On the same day, while playing for the Dunfermline Athletic Club against the Lochgelly United, in a match at Dunfermline, a young man had one of his legs fractured; and during a match between the Birmingham Wycliffe and the Lichfield Leomansley Clubs a scrimmage occurred, and the Wycliffe captain sustained a fracture of his leg above the ankle.

VOLUNTEER MEDICAL ASSOCIATION.—The usual quarterly meeting of the council was held at 101, Great Russell-street, on Wednesday, Jan. 27th. A resolution was passed expressing respectful sympathy and condolence with the president, Field Marshal H.R.H. the Prince of Wales on the melancholy event of the death of H.R.H. the Duke of Clarence and Avondale. The draft of the annual report for 1891 was read and approved, and it was ordered to be printed and circulated. The report of a committee lately appointed to revise the regulations for the Ambulance Challenge Shield was received, and the regulations for the competition as amended by the committee were adopted. Entries for the challenge shield must be sent to the hon. secretary before April 30th. The next meeting of council will be held on April 27th.

OVERLOADING STEAMSHIPS.—The stipendiary magistrate at Cardiff last week inflicted the maximum fine of £100 each in three cases of overloading steamships at Port Said, Gibraltar, and at Bilbao. In giving his judgment he stated that the jeopardy and loss of human lives directly and clearly attributable to overloading had officially been brought to his notice.

WINDSOR AND ETON ROYAL DISPENSARY AND INFIRMARY.—During the year 1891, 291 patients had been admitted into the institution, the largest record for some years, and 4257 out-patients were attended at the dispensary, or treated at their own homes. The income had fallen off considerably during the year; but, taking into consideration the great amount of sickness and distress which had been prevalent, the balance-sheet was a favourable one.

BRISTOL ROYAL INFIRMARY.—At a special meeting of the governors, held on the 26th ult., to consider a proposed alteration in the rules in reference to the mode of election to vacancies on the honorary medical and surgical staff, it was unanimously resolved that: "Every vacancy in the honorary medical and surgical staff shall be filled up by a committee of election, consisting of president, vice-presidents, and consulting physicians and surgeons, including the obstetric physician and ophthalmic surgeon, and members of the committee of management, together with twenty-one governors, to be appointed only at the general board to be held in March in each year. Whenever a vacancy may occur in the office of physician, surgeon, obstetric physician, ophthalmic surgeon, dental surgeon, assistant physician, or assistant surgeon, the committee of management shall, upon announcement of the vacancy, summon a meeting of the committee of election to fill the same, on a day to be notified on the summons, and proceed to the election accordingly." It was stated that this alteration would reduce the expense to the candidates, and abolish the necessity of canvassing.

GIVEN, J. C. M., L.S.A., has been appointed Assistant Medical Officer of the Derby Borough Asylum.

GOUGH, J. HARLEY, L.R.C.P. Lond., M.R.C.S., has been appointed Honorary Surgeon to the Tavistock Cottage Hospital.

GRIFFITH, JAS. DE B., M.B., M.Ch. Dub., has been appointed a Medical Officer for the Sunbury Lunatic Asylum, Victoria, Australia.

HEARD, ROBERT LYNN, M.B., B.Ch. R.U.I., has been appointed Medical Officer to the Monkstown Parochial Benefit Society.

HILL, T. EUSTACE, M.B., C.M. Edin., B.Sc., has been reappointed Medical Officer of Health for South Shields.

HUME, G. H., F.R.C.S. Edin., has been appointed Consulting Surgeon to the Children's Hospital, Newcastle-on-Tyne.

HUNTER, W. L., M.D., B.Ch., D.P.H. Eng., has been appointed Medical Officer of Health to the Pudsey Local Board.

JONES, GEO. F., M.R.C.S., has been appointed Medical Officer of Health for Southend.

KENNEDY, F. W. M.D., B.Ch., B.A.O.Dub., has been appointed House Surgeon to the Sir Patrick Dun's Hospital, Dublin.

LOVERIDGE, A. W., M.R.C.S., has been appointed Honorary Surgeon to the Newport (Mon.) Infirmary.

MACAULAY, THOS., M.R.C.S., L.M., has been reappointed Medical Officer of Health for the Market Harborough Rural District.

MUIR, JAMES M. M., M.B., M.Ch. Glasg., has been appointed a Public Vaccinator at Woodend, Victoria, Australia.

NORRIS, L. FREDK., M.B., C.M. Glasg., has been appointed Junior House Surgeon to the Borough Hospital, Birkenhead.

OZANNE, F. N., L.R.C.P. Lond., M.R.C.S., has been reappointed Medical Officer of the Harrogate Cottage Hospital.

PAGE, FREDERICK, M.D., has been appointed Consulting Surgeon to the Children's Hospital, Newcastle-on-Tyne.

RIDDELL, JOHN S., M.B., C.M. Aberd., has been appointed Medical Officer to the Holborn Lodge of Oddfellows (Caledonian Order).

ROBERTS, N. E., M.B., C.M. Edin., has been appointed Visiting Physician to the Granton-street and Parkhill Hospitals, Liverpool.

ROBERTS, C. GORDON, M.A., M.B., B.C. (Cantab.), has been appointed Medical Officer of Health to the Town of Halstead, Essex, and Medical Officer to the Second Division, and Public Vaccinator to the First and Second Divisions of the First District, Halstead Union.

SHARMAN, ERIC H., M.R.C.S., L.R.C.P., has been appointed House Surgeon to the Hospital for Sick Children, Great Ormond-street, W.C.

SPENCER, W., L.R.C.P., L.R.C.S. Edin., has been reappointed Medical Officer of Health for the Borough of East Retford.

STEELE, H. O., M.R.C.S., has been reappointed Medical Officer of Health for Gomersal.

SULLIVAN, EDWD. F., M.D., M.Ch., L.M. R.C.P. Irel., has been appointed Health Officer for the North Yarrawonga Shire, Victoria, Australia.

TAYLOR-GENGE, T., L.D.S., has been appointed Dental Surgeon to the Bristol General Hospital, vice T. Cooke Parson, M.R.C.S., L.D.S., deceased.

WILLIAMS, NEVILLE, M.B. (Cantab), M.R.C.S., has been reappointed Medical Officer of the Harrogate Cottage Hospital.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement.

CAPE COPPER COMPANY.—Assistant Surgeon for Cape Colony. (Apply, by letter only, to the Secretary, No. 9, Queen-street-place, London, E.C.)

CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, Victoria Park, E.—Assistant Physician. (Apply to the Secretary. Office, 24, Finsbury-circus, E.C.)

DENTAL HOSPITAL OF LONDON, Leicester-square.—Two Assistant Dental Surgeons.

DISTRICT INFIRMARY, Ashton-under-Lyne.—Junior House Surgeon and Dispenser. Salary £50 per annum, with board and lodging.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.—Resident Medical Officer for two years. Salary £80 per annum, with board, lodging, and washing.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E. — House Physician. Board and lodging provided.

GENERAL HOSPITAL, Birmingham.—House Governor. Salary £300 per annum, with board and apartments.

HOSPITAL FOR WOMEN, Soho-square, London.—House Physician for six months. Salary £30 for that period.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton.—Assistant Physician.

KENT COUNTY LUNATIC ASYLUM, Chartham, near Canterbury.—Medical Superintendent. Salary £600 per annum, with unfurnished house, gas, washing for himself and family, and produce of garden.

LONDON LOCK HOSPITAL AND ASYLUM, Harrow-road, W., and 91, Dean-street, Soho, W.—Surgeon to in-patients and out-patients at 91, Dean-street, Soho, W., for two years.

LONDON COUNTY ASYLUM, Cane-hill, Coulsdon, Surrey.—Fourth Assistant Medical Officer. Salary £150 per annum, rising by £5 to £160, with board, lodging, and washing.

LONDON HOSPITAL, Whitechapel, E.—Assistant Surgeon.

METROPOLITAN HOSPITAL, Kingsland-road, N.E.—Surgeon.

MR. E. J. HARWOOD, 18, Ely-place, Holborn, E.C.—Medical Officer.

NORFOLK COUNTY ASYLUM, Thorpe, Norwich.—Senior Assistant Medical Officer for five years. Salary £160 per annum, with board, lodging, and washing.

PARISH OF LOCK GOILHEAD AND KILMORICK, N.B.—Medical Officer. Salary £70 per annum.

QUEEN'S HOSPITAL, Birmingham.—Casualty Surgeon. Annual honorarium £50.

ROYAL HOSPITAL FOR CHILDREN AND WOMEN, Waterloo-bridge-road, S.E.—Resident Medical Officer. Salary £70 per annum, with board and apartments.

SOUTH SHIELDS UNION.—Medical Officer for the Union Workhouse. The salary, which will include remuneration for all operations and accouchements, will be at the rate of £250 per annum, together with a fee of 1s. 6d. for each child vaccinated in the Workhouse.—(Apply to the Clerk to the Guardians, Union Offices, South Shields.)

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, Albert Embankment, S.E.—The Chair of Chemistry.

UNIVERSITY OF GLASGOW.—Three Assistant Examiners. The annual fee to each Examiner is £30, and the term of office in each case is four years from April 1st next.

Births, Marriages, and Deaths.

BIRTHS.

SILCOCK.—On Feb. 1st, at 52, Harley-street, W., the wife of Arthur Quarry Silcock, M.D., B.S. (Lond.), F.R.C.S. Eng., of a son.

HANLY.—On Jan. 29th, at Ormskirk, the wife of Dr. J. J. Hanly, M.A., of a son.

FAWSSETT.—On Jan. 31st, at Lewes, Sussex, the wife of Frank Fawssett, M.B., B.S. Lond., of a daughter.

INKSTER.—On Jan. 24th, at Broomhill Lodge, Sheffield, the wife of S. Macaulay Inkster, M.D., of a daughter.

MANLEY.—On Jan. 24th, at New-street, West Bromwich, the wife of Dr. Herbert Manley, of a son.

COLLIER.—On Jan. 29th, at St. Mary's Entry, Oxford, the wife of WM. Collier, M.D., of a son.

JAMES.—On Jan. 19th, at Cazenove-road, Stamford-hill, N., the wife of C. A. James, L.R.C.P., M.R.C.S., D.P.H. Eng., of a son.

HAKE.—On Jan. 30th, at Inverness-terrace, Fulham, S.W., the wife of Dr. H. Wilson Hake, of a son.

OPENSHAW.—On Jan. 29th, at Wimpole-street, Cavendish-square, W., the wife of T. Horrocks Openshaw, M.S., F.R.C.S. Eng., of a son.

SMELT.—On Feb. 1st, at The Villa, Newent, Glos., the wife of Frank Hayes Smelt, Surgeon, of a son.

MURDOCH.—On Feb. 2nd, at Morningside-road, Edinburgh, the wife of T. M. Burn Murdoch, M.B., of a son.

MARRIAGES.

ROUTH—WATSON.—On Jan. 28th, at Rosehall U. P. Church, Edinburgh, by the Rev. Lewis Davidson, Mayfield Free Church, Randolph Henry Felix Routh, M.R.C.S., L.R.C.P., of Bridgewater, Somerset, youngest son of C. H. F. Routh, M.D., of Montagu-square, London, to Jean Gladstone, eldest daughter of Walter Watson, M.D., of Edinburgh, late of Midcalder.

CONWAY—FORSYTH.—On Jan. 27th, at the Parish Church, Sale, Basil Wiseman Conway, M.R.C.S., L.R.C.P., of Longsight, Manchester, eldest surviving son of the late Edwin Conway, of Stalybridge, to Jane, only daughter of the late Henry Arthur Forsyth, of Charlton Drive, Sale, Cheshire.

EADES—SAVAGE.—On Jan. 27th, at St. Anne's Church, Wandsworth, S. O. Eades, L.R.C.P., L.R.C.S. Edin., of Ipswich, to Teresa Julia Mary Savage, of Struan, Wandsworth-common, S.W.

RICHARDSON—LEVEAUX.—On Jan. 28th, at Hornsey Church, Alfred Ernest Richardson, M.D., M.R.C.S., of Tamworth, to Kate Josephine, eldest daughter of the late Mr. E. H. Leveaux, the Grange, Brookgreen, W.

DEATHS.

ADAMS.—On Jan. 31st, at Tower Lodge, Regent's-park-road, William Adams, F.R.C.S., J.P., aged 65.

BUTLER.—On Jan. 21st, at Cosham, Hants, suddenly, Edward Jones Butler, B.A., M.D., Fleet Surgeon R.N. (retired), second surviving son of the late John Butler, Leinster-square, Rathmines, Dublin, aged 54.

FROST.—On Feb. 3rd, Helena Maria, the dearly beloved wife of John Kingdon Frost, M.R.C.S., and only daughter of F. W. Sutton, Esq., Inspector of Machinery R.N. (retired), aged 29.

GRAY.—On Jan. 2nd, John Temperley Gray, L.R.C.P. Lond., M.R.C.S., of Bombay.

HICKSON.—On Jan. 31st, at Norland-square, London, W., Albert Thomas Hickson, M.A., M.D., sixth son of the late W. M. Hickson, R.M.

JACKSON.—Washed overboard in a gale, John Simpson Matthew Jackson, B.A., Senior Moderator, M.B. T.C.D., L.R.C.S.I., Surgeon ss. *Angola*, eldest son of Sir Robert W. Jackson, Eglinton, Sandymount, Dublin.

MACDONALD.—On Jan. 31st, at Kirkdale, Liverpool, A. D. Macdonald, M.D., C.M. Edin., aged 37.

MUGGERIDGE.—On Jan. 19th, at Balham, Henry Harris Muggeridge, M.R.C.S., L.L.D., aged 77.

OWEN.—On Jan. 22nd, at Brecon, Robert Owen, L.R.C.P., L.R.C.S. Edin., aged 39.

PAGET.—On Jan. 29th, at Cambridge, Sir George E. Paget, K.C.B., M.D., F.R.S., Regius Professor of Physic in the University of Cambridge, and Fellow of Gonville and Caius College, aged 83.

STADDON.—On Jan. 29th, at Silent-street, Ipswich, John Hart Staddon, M.R.C.S., L.R.C.P., aged 61.

STURTON.—On Jan. 30th, at Stevenage, Herts, H. W. S. Sturton, M.R.C.S., of Greenwich, second son of the late William Sturton, M.R.C.S., L.S.A., of Croydon.

WARBURTON.—On Jan. 23rd, at his residence, Low Croft House, Wibsey, near Bradford, Yorkshire, Henry Alfred Warburton, M.R.C.S., L.S.A., aged 73 years.

WHITE.—On Jan. 26th, in London, from acute pneumonia, arising from influenza, Samuel Gamble White, Brigade Surgeon, retired, aged 53.

WOLFF.—On Jan. 31st, at Gloucester-gardens, Abraham Wolff, F.R.C.S., aged 73.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births Marriages, and Deaths.

Medical Diary for the ensuing Week.

Monday, February 8.

ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Tuesday, Wednesday, Friday, and Saturday at the same hour.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations daily at 10 A.M.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M., and each day at the same hour.

CHELSEA HOSPITAL FOR WOMEN.—Operations, 2.30 P.M.; Thursday, 2.30.

HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.

METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.

ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.

CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and each day in the week at the same hour.

UNIVERSITY COLLEGE HOSPITAL.—Ear and Throat Department, 9 A.M.; Thursday, 9 A.M.

LONDON POST-GRADUATE COURSE.—Royal London Ophthalmic Hospital: 1 P.M., Mr. Wm. Lang: Conjunctival Affections.—Great Northern Central Hospital: 8 P.M., Dr. Galloway: Gastro-Intestinal Tract.

MEDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. J. W. Carr: Enlargement of the Spleen in Young Children.—Dr. J. S. Keser: The Treatment of some forms of Chronic Bronchitis by the Water of Weissenburg (Switzerland).

Tuesday, February 9.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.; Fridays and Saturdays at the same hour.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at same hour. Ophthalmic Operations on Monday at 1.30 and Thursday at 2 P.M.

ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.

ST. MARK'S HOSPITAL.—Operations, 2 P.M.

CANCER HOSPITAL, BROMPTON.—Operations, 2 P.M.; Saturday, 2 P.M.

WESTMINSTER HOSPITAL.—Operations, 2 P.M.

WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Consultations, Monday, 2.30 P.M. Skin Department, Monday and Thursday, 9.30 A.M. Throat Department, Tuesdays and Fridays, 1.30 P.M. Electro-therapeutics, same day, 2 P.M.

ROYAL INSTITUTION.—3 P.M. Professor V. Horsley: The Brain.

LONDON POST-GRADUATE COURSE.—Hospital for Skin Diseases, Blackfriars: 4 P.M., Mr. J. Hutchinson: Lichen Planus.—Bethlem Hospital: 2 P.M., Dr. Hyslop: Puerperal and Lactational Insanity.—Charing-cross Medical School: 8 P.M., Dr. Potter: The Sequelæ of Abortion.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—Mr. Holmes will exhibit a Patient on whom Pirogoff's Amputation was performed twelve years ago.—Dr. Mitchell Bruce and Mr. A. Marmaduke Sheild: Gelatinous Degeneration of Hydatid Cysts.—Dr. Archibald E. Garrod: The Changes in the Blood in the course of Rheumatic Attacks.

Wednesday, February 10.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.

MIDDLESEX HOSPITAL.—Operations, 1.30 P.M.; Saturdays, 2 P.M. Obstetrical Operations, Thursdays, 2 P.M.

CHARING-CROSS HOSTITAL.—Operations, 3 P.M., and on Thursday and Friday at the same hour.

ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M.; Saturday, same hour.

LONDON HOSPITAL.—Operations, 2 P.M.; Thursday & Saturday, same hour.

ST. PETER'S HOSPITAL, COVENT-GARDEN.—Operations, 2 P.M.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.

GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 1.30 P.M.; Skin Department, 1.45 P.M.; Saturday, 9.15 A.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M., and on Saturday.

CHILDREN'S HOSPITAL, GREAT ORMOND-STREET.—Operations, 9.30 A.M. Surgical Visits on Wednesday and Saturday at 9.15 A.M.

LONDON POST-GRADUATE COURSE.—Hospital for Consumption, Brompton: 4 P.M., Dr. Green: Cases in the Wards.—Royal London Ophthalmic Hospital: 8 P.M., Mr. J. B. Lawford: Optic Nerve Atrophy. Parkes Museum: 1 P.M., Dr. Louis C. Parkes: Defective Sanitary Arrangements in Houses, and their Effects upon Health.

Thursday, February 11.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M. Surgical Consultations Wednesday, 1.30 P.M. Ophthalmic Operations, Friday, 1.30 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Ear and Throat Department, 9 A.M.

ROYAL INSTITUTION.—3 P.M. Professor E. Ray Lankester: Some Recent Biological Discoveries.

LONDON POST-GRADUATE COURSE.—Hospital for Sick Children, Great Ormond-st.: 4 P.M., Dr. Barlow: Illustrations of Abdominal Disease in Children.—National Hospital for the Paralysed and Epileptic: 2 P.M., Dr. Buzzard: Cases in the Hospital.—London Throat Hospital, Gt. Portland-st.: 8 P.M. Dr. Woakes: Necrosing Ethmoiditis.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY (Great Northern Central Hospital).—9 P.M. Dr. Lewis Jones: Electricity as an Aid to Medical and Surgical Diagnosis and Treatment.

BRITISH GYNÆCOLOGICAL SOCIETY.—8.30 P.M. Specimens will be shown by Dr. Granville Bantock. Dr. Heywood Smith: Subperitoneal Hysterectomy.

Friday, February 12.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.

LONDON POST-GRADUATE COURSE.—Hospital for Consumption, Brompton: 4 P.M., Dr. Green: Cases in the Wards.—Bacteriological Laboratory, King's College: 11 A.M. to 1 P.M., Professor Crookshank: Tuberculosis (Examination of Sputum, &c.).—Charing-cross Medical School: 8 P.M., Dr. Potter: The Uterine Sound.

CLINICAL SOCIETY OF LONDON.—Dr. Lees: Three cases of Perforation of the Vermiform Appendix.—Mr. Page: (1) A case of Acute Appendicites, Removal of Appendix, Recovery; (2) A case of Relapsing Appendicites, Operation, Recovery.—Mr. Stephen Paget: An unusual case of Sloughing of the Vermiform Appendix.—Mr. Bland Sutton: A case of Cholelithiasis, Removal of Impacted Gall-stones through an Incision in the Common Duct; Recovery.

ROYAL INSTITUTION.—9 P.M. Mr. G. J. Symonds: Rain, Snow, and Hail.

Saturday, February 13.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; and Skin Department 9.15 A.M.

LONDON POST-GRADUATE COURSE.—Bethlem Hospital: 11 A.M., Dr. Hyslop: Climacteric Insanity.

ROYAL INSTITUTION.—3 P.M. Right Hon. Lord Rayleigh: Matter, at Rest and in Motion.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editors."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

We cannot undertake to return MSS. not used.

WINE COMPANIES AND MEDICAL ADVERTISEMENTS.

Dr. J. Fletcher Little directs our attention to the objectionable way in which the medical virtues of a certain wine are described in a very widely circulated pamphlet. We agree with him. It is surely possible to advertise a wine without entering into all the details of chlorosis, the mysterious joys of maternity, &c. Such a parade of questionable learning is not likely to conciliate the medical profession.

O'DWYER'S TUBES.

To the Editors of THE LANCET.

SIR,—Having read in your issue of Jan. 23rd Dr. Sutherland's excellent report of a case in which a twice-saved life was ultimately lost from the slipping of an intubation tube into a bronchus, I have noticed that the tube is described as being of size No. 3, two inches and a quarter long. This size is the largest in the sets of intubation tubes usually sold, and at the time of the accident was, I believe, the largest in vogue in England. Dr. O'Dwyer intends this size for children of from ten to twelve years of age. For adults he used much larger vulcanite tubes, or, in cases of narrow stricture, tubes with much wider heads. Messrs. Weiss of Oxford-street have promised to copy O'Dwyer's vulcanite tubes for adults. The case may prejudice the prospects of intubation, unless it be borne in mind that such an accident, unavoidable last March, cannot occur in treatment with the more recent tubes.—I am, Sirs, faithfully yours,

HORACE COLLIER, F.R.C.S.

Children's Hospital, Great Ormond-street, Feb. 2nd, 1892.

NEW SPINAL JACKET.

DR. J. MARSHALL HAWKES describes in the *Philadelphia Medical News* a new kind of jacket which he has successfully used in a spinal case, to the great relief of the patient. It consisted of pure jute fibre free from clay and wood pulp; and from its very light weight, its imperviousness to moisture, and the efficient support which it gave it was found to be much more satisfactory than plaster. A model of the patient's body was made by winding wet plaster bandages round her from the anterior superior spinous processes of the ilia to the lower axillary borders. A plaster caste made from this mould was modelled so as to preserve the natural anatomical contour of the patient, and on this cast the paper, cut into strips half an inch wide, was laid in successive layers. It was then divided down each axillary line and laced with elastic, thus allowing of some expansion during respiration. The total weight of such a jacket is only about twelve ounces, and its advantages over the cumbrous plaster apparatus are obvious. Dr. Hawkes has also made splints in a similar way, and has found them to be very convenient and thoroughly efficient.

Mr. Mayo Robson (Leeds).—The paper will appear next week.

Snowdrop should consult his medical adviser.

POSTAGE STAMPS AND INFECTION.

To the Editors of THE LANCET.

SIRS,—As any hypothesis regarding the spread of influenza may be suggestive, I venture to offer one that I have not seen noticed before.

During the first epidemic the Post-office officials seemed to be among the first affected both in this country and abroad, and one of the first cases reported in England was in the Foreign Office, when Lord Salisbury was attacked. May it not be that in these cases the source of infection was the saliva used to moisten the gummed surface of stamps and edges of envelopes, the mucilage perhaps being a suitable menstruum for the development of bacilli? In trying to follow up the probability of this theory I have been struck by the number of instances in which patients attribute an attack to a letter received from an infected house or district. Of course, this, if a source, can be only one of many, yet one that can easily be destroyed, hence worth attention.

I am, Sirs, yours truly,

Feb. 1st, 1892. H. L. G.

DR. COLLIE.

To the Editors of THE LANCET.

SIRS,—To-day our much-esteemed colleague has quitted the scene of his twenty-one years' arduous and risky labours. He was not permitted to depart without a warm expression of affectionate regard from all who had the pleasure of serving under him in the Eastern Hospital. A meeting was held, and a testimonial presented, which had been subscribed for by the staff of *employés* as a small recognition of the high esteem in which he was held, and their warm appreciation of his long and faithful services. Dr. Collie (who was much affected) briefly returned thanks, and the meeting separated. Now it occurs to me that the present would be a suitable opportunity for the profession to testify by a substantial testimonial its sense of Dr. Collie's high personal worth and professional attainments. If THE LANCET would give its powerful influence to forward that object, I doubt not the response would be a warm one.

I am, Sirs, your obedient servant,

Jan. 29th, 1892. M.D., L.R.C.P. LOND.

A DANGER IN DOUCHING.

To the Editors of THE LANCET.

SIRS,—A point worth remembering when douching the abdominal cavity after ovariotomy &c. is that the water, though poured into receptacle a moment before out of a boiling kettle will, when allowed to flow from end of rubber tube, be found almost quite cold for about ten seconds, the heat being abstracted by the length of tubing (generally six feet or so) before exit. I only discovered this quite accidentally on a patient exclaiming how cold the water was while douching the vagina, when I had a moment before almost filled the receptacle from the boiling kettle, and added cold water to make it a bearable heat. As I have not heard or seen notice of this fact I think it worth while drawing attention to it, as the shock of a cold stream of water turned on the abdominal viscera, under the impression that the water was hot, might make all the difference in the subsequent result of an operation.

I am, Sirs, yours faithfully,

Dublin. ALEXANDER DUKE.

"THE MIASMATIC THEORY OF ACUTE RHEUMATISM."

To the Editors of THE LANCET.

SIRS,—Please allow me to correct an unfortunate error which crept into my letter to THE LANCET last week—viz., the attribution of the miasmatic theory of acute rheumatism and the salicin treatment to Sir D. Maclagan, instead of to Dr. T. J. Maclagan, of 9, Cadogan-place, London. I regret the mistake, and hasten to have it rectified. Dr. Maclagan is deserving of all the honour which his professional brethren can give; for who can estimate the full extent of the relief which he has afforded to suffering humanity by suggesting the use of salicin in acute rheumatism?—I am, Sirs, yours faithfully,

Harrogate, Feb. 3rd, 1892. J. GORDON BLACK.

CATARACT COMPLICATED WITH GRAVES' DISEASE.

DR. S. N. LOSHECHNIKOFF publishes in a recent number of the *St. Petersborger Medicinische Wochenschrift* a case of cataract, which he had extracted in a patient aged twenty who was the subject of Graves' disease. There was soft cataract in both eyes, with considerable exophthalmos. Pulse 110. The urine contained neither albumen nor sugar. Six convulsive seizures had taken place before the sight appeared affected. The author extracted the left cataract upwards, having been able to save the sphincter iridis in the iridectomy. The lens was easily pressed out. The iris was replaced in a good position, but the margins of the corneal wound remained patent. The wound was washed with sublimate, and eserine applied before the dressing. When the latter was changed, three days afterwards, the chamber was found of good depth, but there were hyphæma and œdema of the conjunctiva, and the patient complained of pain. The margins of the wound were in good apposition. Three days later the hyphæma and œdema were less, but the former had increased again in another three days, and the colour of the iris had lost its clearness. Pulse 98. A week later, subacute iritis came on, which ran a course of four weeks. Double iridectomy was then performed, there being a slight fissure and a little loss of vitreous. Three days later the cornea had become opaque, and all dressing was then discontinued. The iris had become transparent in ten days, but was covered by opaque cornea. Fowler's solution was administered, but the patient did not bear it well, and the pulse had risen to 100. Digitalis was substituted and iridectomy performed for a second time, with an ultimate result of V. $\frac{1}{10}$.

Mr. R. E. Johnson might consult with advantage the tariff of charges published by the Manchester Medico-Ethical Association.

Dreamer.—Dr. Hack Tuke: "Sleep-walking and Hypnotism," 1884.

A CORRECTION.

To the Editors of THE LANCET.

SIRS,—I shall esteem it a favour if you will allow me through your columns to correct a mistake in my address, which occurs in the Medical Directory for 1892, on page 931. My address is there given as 11, Palatine-street, Harpurhey, whereas it should be, as it has been for some years past, 14, St. John-street and 3, Stanley-grove, Oxford-road. I should not have troubled you in this matter but that several important letters and telegrams have already been sent to the wrong address by members of the profession; and to obviate such mistakes in future I would ask those who have the Directory for 1892 to make the necessary correction.

I am, Sirs, yours faithfully,

Manchester, Feb. 2nd, 1892. JAMES ROSS, M.D., F.R.C.P. Lond.

"INFLUENZA ROBBED OF ITS TERRORS" IN LIVERPOOL.

Medicus is naturally indignant at a vulgar handbill vaunting the powers of a remedy called "Antigrippe," "Bloodsteriliser," and other powerful names, the more so as he is assured that it is the work of a qualified medical man. We advise our correspondent to be sceptical on this point.

Eyeball.—Ophthalmology: Nettleship, Lawson, Berry, Juler. Diseases of Children: Ashby and Wright, Eustace Smith, Goodhart.

Dr. R. J. Shepherd (Pau).—The paper will appear shortly.

COUCHAIDE.

To the Editors of THE LANCET.

SIRS,—Will any good brother who may have had experience of Dr. Diver's "couchaide," figured in Messrs. Down Bros.' catalogue, p. 505, kindly say how far it meets with approval, and if any precaution is necessary in its use? I have long used a firm-fitting binder when labour commences, to be readjusted from time to time, and additional support with the hand or towel during the severer pains. But the comments of experienced accoucheurs on this contrivance will be gratefully received by Yours most truly,

January 31st, 1892. F.R.C.S.

Spes.—Our correspondent will see from an announcement in another column that the name will probably be changed to "Gresham."

Dr. Campbell (Garlands).—Yes, very soon.

THE HODGSON FUND.

To the Editors of THE LANCET.

SIRS,—Please acknowledge the following amount for the above fund.

Mr. C. J. Stocker, Forest gate, £1 1*s*.

I am, Sirs, faithfully yours,

J. PHILLIP TOPPING.

271, Romford-road, Forest-gate, Feb. 3rd, 1892.

ERRATUM.—In Mr. Jessett's letter on "A Suggestion for the Treatment of Irreducible Intussusception of the Bowels," which appeared in our issue of Jan. 23rd, twenty-three lines from the bottom of the page, the following sentence occurs: "Even if this should not be the case, three or four quill sutures, &c." It should be "three or four *quilt* sutures."

IDEAL FOODS.

LONDON.] FEBRUARY 13TH. [1892.

ZYMINISED MEAT and MILK SUPPOSITORIES for Rectal Alimentation.

Physiologists are unanimous in condemning GELATINE as a basis for peptone suppositories, for this mixture is one of the best culture-media for BACTERIA, therefore we have prepared these suppositories with pure peptones and COCOA BUTTER; they are easily introduced, perfectly absorbed, never cause intolerance, and ARE PERFECTLY STERILE.

The ZYMINISED MEAT SUPPOSITORIES were thoroughly tested clinically by Dr. Barlow in cases after surgical operations, gastric ulcer, or when for any reason it was found desirable to rest the stomach; in every case the suppository was perfectly absorbed, and afforded excellent results. Mr. Bowreman Jessett, THE LANCET, Oct. 24th, 1891, records the successful operation of combined pylorectomy and gastro-enterostomy when the patient was fed with *zyminised meat suppositories.*

Zyminised Meat and Milk Suppositories are supplied to the Profession in boxes of 1 dozen at 1s. 10d. per box.

ZYMINE PEPTONISING POWDERS (Fairchild).

These are so called because they convert proteids, albumens, and fats into soluble *peptones*, and readily assimilable substances. Whenever it is proposed to peptonise milk only, and that continuously, the Zymine Peptonising Powders (Fairchild)* will be found the most convenient form to use for obvious reasons.

"Fairchild Peptonising Powders (Zymine)—These are very useful for peptonising milk, and especially for use in the case of infants brought up by "bottle.'" "Manual of Clinical Dietetics," Dr. Burnet. In those cases, however, where strict economy is a matter of considerable moment, the plain Zymine can be used.

The Zymine Peptonising Powders (Fairchild) in glass tubes, a dozen in a box, each tube containing 5 gr. of Zymine and 15 gr. of Soda Bicarb., sufficing to predigest a pint of milk or beef-tea.

The BRITISH MEDICAL JOURNAL, referring to the value of predigested foods by the **ZYMINE** method, says: "It has proved useful in many hands in *uræmic vomiting, gastric catarrh, pernicious anæmia, gastric ulcer, pyloric and intestinal obstruction.* ITS INTRODUCTION HAS PROBABLY DONE MORE THAN ANY OTHER THERAPEUTIC MEASURE TO LESSEN INFANT MORTALITY."

IMPORTANT NOTE.—*A complete list of recipes for the preparation of peptonised foods is supplied with each box of the powders, or will be sent post free to any medical man on request.*

ZYMINE PEPTONISING POWDERS (FAIRCHILD) supplied to the profession in boxes containing 1 dozen tubes at 1s. 2d. each. Retail, 1s. 6d. per box.

*Beware of imitations of these Peptonising Powders—always see that the name FAIRCHILD is on the package, as Substances of an entirely different character are being sold in the market under the name of Peptonising Powders.

THE VERDICT CONFIRMED.

"The therapeutic value of Extract of Malt rests not only upon the presence of important food elements, as **dextrins, maltose,** and **alkaline phosphates,** but on the peculiarly active substance, **DIASTASE** which is concerned in **converting the starch of farinaceous food into the more assimilable products.** The masterly researches of Messrs. C. O. Sullivan, Brown, Heron, and Morris have shown that diastase is without action upon unaltered starch, or starch as it occurs enclosed in the cell. As soon, however, as the cellulose envelope of the granule is broken, either by bruising or boiling, the starch granulose rapidly undergoes conversion or hydrolysis, even in the cold, into maltose and a variety of dextrin called erythro-dextrin. It is some time now since we had occasion to examine the well-known and much-used **KEPLER EXTRACT OF MALT. Messrs. Burroughs, Welcome, & Co. evidently keep pace with the newest scientific facts,** which every day contribute towards making this kind of preparation **PERFECT.** The flavour has been further improved, and the delicacy of the colour contributes largely to its attractive appearance."—THE LANCET, Jan. 31st, 1891.

USEFUL NOTES.

A well-known special Physician for the **Diseases of Children** has made extensive trials with the **KEPLER EXTRACT OF MALT** in his clinic, and he informs us that it is worthy of the most careful attention. He finds half a teaspoonful of the Extract added to the contents of the nursing bottle **completely prevents the casein of the milk curdling in large clots,** and thus removes one of the chief causes of infantile diseases. It also digests the starch of farinaceous foods, and renders them easy of assimilation; even the most weakly little subjects over six months of age rapidly thrive on a diet of wheat-flour, milk, and Kepler Extract of Malt.

It is self-evident, therefore, that it will be of the greatest service as an addition to the diet of invalids and convalescents.

The Kepler Extract of Malt and Kepler Solution of Cod Liver Oil in Extract of Malt are supplied to the Profession in ¾-lb. and 1½-lb. bottles at 1/8 and 3/- each.

BURROUGHS, WELLCOME, & CO., SNOW HILL BUILDINGS, LONDON, E.C.

Specimens sent to Medical Men post free on request.

THE KEPLER ESSENCE OF MALT

(ESSENTIA MALTI, KEPLER).

IT is very generally conceded by the Medical Profession that **Diastase** is really the most *important constituent of Extract of Malt;* and with a view to affording a reliable means for prescribing this important aid to digestion in a definitely concentrated form, we have introduced the **Kepler Essence of Malt.** This is a liquid preparation of about the same consistency as glycerine, and is virtually *a saturated solution of Diastase and the Natural Phosphates* as existing in Barley Malt. It is therefore a valuable chemical food both for bone and brain substance, and a powerful digestive of farinaceous food, unsurpassed by any similar product yet introduced.

There is an entire absence of the intense sweet flavour and mawkish taste so generally prevalent in fluid malt preparations, and which render them so repugnant to the palate.

The KEPLER ESSENCE OF MALT makes a most delicious drink when mixed with aerated waters, milk, or even plain water, and should be very much appreciated as an ideal nutritive beverage.

The KEPLER ESSENCE OF MALT is supplied to the Profession in bottles at 1s. 2d. each.

BURROUGHS, WELLCOME, & CO., SNOW HILL BUILDINGS, LONDON, E.C.

Specimens sent to Medical Men free on request.

The Harveian Lectures

ON

COMMON NEUROSES, OR THE NEUROTIC ELEMENT IN DISEASE AND ITS RATIONAL TREATMENT.

Delivered before the Harveian Society of London, Nov. 19th and 26th and Dec. 2nd, 1891.

BY JAMES F. GOODHART, M.D., F.R.C.P.,
PHYSICIAN TO GUY'S HOSPITAL.

LECTURE III. (*Concluded.*)

COMING next to constipation, it is hardly necessary to insist that there are two predominant factors in its production—the influence of the nervous system direct, and the influence of habit. The influence of the nervous system shows itself by a phlegmatic reaction to the natural stimuli, and this may be either an action natural to the individual; or an unhealthy one, due to a lowered vitality of the centres involved. There is no difficulty in establishing the power of the nervous system to determine the complaint when we consider how in several morbid conditions—melancholia in particular, but in hemiplegics, acute and chronic inflammatory conditions, and so on—one and the other keep time together; and there can be no question that, although the derangement of the bowels is an important element for consideration in promoting the cure, the morbid condition of the nervous system precedes. It is with the bowel as with the stomach, as in a case already noted, the sleeplessness always *preceded* the flatulent dyspepsia. Moreover, who has not seen several times the milder forms of nerve disturbance—the simple depression of spirits, the transient glycosuria that occurs in the overworked, &c.—closely followed by obstinate constipation? It is often thought that the benefit that accrues on a good clear out shows that some of these states are the result of the fouled flues. No doubt this is so sometimes—it cannot be so always; and there is no doubt that the intestine, as regards constipation, is a highly sensitive organ from which we can very often read the temperament or disposition of the man. But that is not all: it is an index of the state of nervous tone and vigour of the patient; and there is many a state of constipation that is not a case for aperients at all, but requires the liberal use of tonics. But I have something to say also on the subject of habit. It is sufficiently obvious that the repeated recourse to aperients conduces to constipation and engenders a habit; but perhaps I may say this also—that, impressed as we all become as years go on of the primary importance of maintaining the purity of the *primæ viæ*, we sometimes forget in our advice to the patient that aperients are, after all, only a makeshift, and that they are an evil unless the good they do is undoubted. But the point I wish to make is this—that I have often been told by the chronic *piller*, as an excuse for the persistence in his practice of pill-taking, that he cannot leave it off, because if he does he never has a satisfactory evacuation. He appeals, in fact, to the habit that he has cultivated. But I maintain that in some cases he has not fully considered the question, and that he is not always right. And for this reason. The chronic exhibition of aperient drugs, which are in most cases irritating, engenders a state of periodical excitement in the peripheral nerve endings of the intestine, and ultimately raises the unnatural condition to a *natural* one *for them*. When this time has arrived, the bowel may be described to pass through periods of hunger and periods of satisfaction, according as it is being tickled by the drug that has been given or not. The condition is on all fours with the opium-eater's sensorium, and the bronchial tubes of the chronic asthmatic under the influence of repeated inhalation, and the mucous membrane of the habitual snuffer. And this state extends through the whole length of the intestine probably; but in the present case it is the lower bowel that conveys the sensation of a satisfactory evacuation or not. If it feels the bite of the stimulant, then the individual, through his local sensations, describes himself as satisfied; when the bowel is not under the influence of the stimulant, then there is no adequate sensation of a good clearance, and the patient takes his ease in discomfort. The bowel, like the stomach, takes kindly to good living; but when it has been used to the luxury of such dainties as compound colocynth pill, calomel, aloes, and such like, it, no more than the stomach that has been fed on highly seasoned foods, likes to be deprived of them. The rectum is a very pretty judge of quality, but a very poor one of quantity. So that when a patient, after such means as this, takes to Carlsbad salts and mineral waters and says that they do him no good, and that he must go back to his old remedies, all that he really means is that he cannot control the wishes of his lower bowel any more than the opium-eater can control the cravings of some other part, or the alcoholic his cravings.

But it is not only in constipation that the neurotic tendency of the bowel comes into play. It is even more strikingly seen, if not quite so often, in the explosive diarrhœas that are common in children, and sometimes dog the steps of the individual even to adult age. I can well remember having for some time as one of my out-patients at Guy's Hospital a poor feeble neurotic patient who was in this unhappy condition—that if anyone suddenly came behind him in the street and clapped him on the back with a "Hulloa! how are you, old fellow," his bowels would promptly act. I have never seen another case so bad as that; but I have seen several where they had to walk circumspectly; and the well-recognised condition where the mucous membrane of the intestine seems to be over-sensitive and reacts energetically as soon as food enters the stomach is a similar state of things, and an indication of a temperament. It is certainly a neurotic condition, and may be remedied, as so many of the too sensitive conditions of the nervous system may be, by tonics in part, but much more, I think, by tonics with minute doses of opium added to them.

And this question of diarrhœa leads me on to another very interesting disease that has been called membranous colitis. The term is not a good one because there is no inflammation, but I mean a condition in which casts, more or less perfect, are passed from the bowel. I first made acquaintance with this disease by the kindness of Mr. E. U. Berry of Gower-street many years ago. Since then I have seen many such cases, and they have been all, with one exception, in women who were of a markedly neurotic disposition. I have only once, I think, seen it in a man, and then, interesting to relate, it was associated with the presence of ascarides. The cases I have seen have mostly run on similar characters. Here is one. A young married lady, who dates her troubles from blood-poisoning. She is a highly nervous lady, and always afraid she shall be considered hysterical—a very common dread in the over-nervous. She is able to take little food, for when she eats *solids* they are frequently followed by faintness and sinking sensation in the lower part of the abdomen, the extremities get cold, and she has peculiar twitchings. She is excessively particular about the action of the bowels; when they do not act she has an enema. Every eight or ten days mucous casts are evacuated, and before they come she turns sick, and feels so ill and all-to-pieces that she wishes she might die. She has wasted in the last year or two. This passage of mucus will go on for years, and it does little apparent harm, although the patient is generally spare and mostly of an over-anxious or unhappy disposition. I am very interested in this affection, because it will be in the recollection of my hearers that long ago Dr. Eustace Smith described a condition in children to which he gave the name of mucous disease, in which an excess of mucus is passed from the bowels. I had come to the opinion that this symptom occurred in children either of neurotic inheritance or evidently neurotic in themselves, and in fact that it was in some way a part of the neurotic constitution. I believe now that the mucous disease of children is represented in adults by membranous colitis, and that in *all* the neurotic constitution is a constant feature. What the bond of association may be is a difficult question; possibly a state of the nervous system that is considered adequate to the production of a torpid liver may produce a torpid intestine too, and in some way the mucous surface becomes coated with its own effete products—a parallel, perhaps, to that thick and harsh condition of the skin which is seen in many a case of mental aberration. I should be not adverse to some such hypothesis, if only for being able by such a means to avoid the word catarrh, which, I suppose, would indicate *activity*, not *torpidity*. The symptom, at any rate, goes with a state of sluggish

Digitized by Google

abdominal organs, and it is in no sense one that has even the remotest likeness to inflammation. It is of interest, too, that it should be associated sometimes with the presence of ascarides. This is no more than one would expect, but ascarides are not a common occurrence in adults. And in relation to them I may mention that both for them and mucous disease, when I have opportunity, I am advising the trial of the oleo-resin of copaiba as a possible means of relief, on the recommendation of my friend, Dr. Argles of Wanstead, who tells me that for ascarides he has found this drug administered in capsules one of the most efficacious of remedies for killing the parasites. But in saying this let me not be supposed to be departing from my allection for principles, and that in these things, as in others already mentioned, the disease is a neurotic one, and is certainly much relieved by assuring the patient that it goes on for years without any appreciable harm to the individual, and that a good tonic of arsenic or strychnia and quinine is almost always beneficial, combined with any local remedies for regulating the working of the abdominal viscera. There are other points of interest in this disease that might well be considered, the emaciation particularly; but they fall beyond the line of my present purpose, and therefore I must leave them, though reluctantly.

The consideration of nervous diarrhœa leads on naturally to the subject of stomach ache and abdominal neuralgia, of which I have notes of several interesting cases, but unfortunately no time to relate them. All I can say is that they are exceedingly puzzling, and in several I have hesitated whether there were actual disease, and but slowly come round to the diagnosis of neuralgia. No one feels more than I do that a term of this kind is one of the refuges I have already alluded to and the grave of many a reputation; nevertheless, there is assuredly a severe form of neurosis in the abdominal nerves, sometimes starting in the stomach, sometimes in the intestine, small or great, and many times owning a uterine or pelvic cause, and which, as far as one can approach to certainty, is of functional character. I have purposely excluded from mention the kidney, because I want now to make special reference to that organ as a source of abdominal or renal neuralgia, because it is a somewhat novel subject, and because it falls in with what, on the whole, has been the mainspring of these lectures. I am indebted for much of my train of thought on the subject to a single case, seen eighteen or twenty years ago, that made a great impression on me at the time, and has, without doubt, controlled my advice in many a case since. It was that of a woman who was in Guy's Hospital several times, or for a long time, with all the symptoms of renal calculus. She had severe pain of a paroxysmal kind, and repeatedly passed large quantities of blood in her urine, but that she was also a pronounced neurotic no one doubted who saw her, and I think in consequence she was subjected to an unusually long period of scrutiny. However, after a long while no one who saw her had any doubt that she must have a calculus in one kidney—I forget which at this distance of time. It was at the period when the first talk and performance of nephrectomy were beginning in Germany, and after long waiting it was at last decided to operate in her case, and the kidney was removed. I think it was the first case that was done in this country. The kidney proved to be perfectly healthy, and no stone or evidence of the previous existence of one was to be found. The patient died from the operation in a day or two, and I made the post-mortem examination, and the other kidney, bladder, and indeed all parts of her body, were absolutely healthy. I have ever since felt obliged to admit that all the symptoms of stone in the kidney may be present, even to the passage of blood from the organ, and yet no stone exist; and the only explanation that seems possible is that under the stress of some severe abdominal nerve-storm emanating from the kidney in a neurotic subject, the circulation of the part may become disturbed, and so the passage of blood was to be explained. I admit, for no one nurtured on the rude facts of morbid anatomy as I have been could help doing so, that in such an explanation there is always a lurking spectre of mistake somewhere; nevertheless, I cannot now but think that it does fall in with clinical experience. And for that reason tender and movable kidneys form a subject of the greatest practical importance. In the last ten years I have come across many cases of this sort, and I have taken notes of seventeen cases. Two facts call for notice: first, the large preponderance of women affected, thirteen to four; and, secondly, that both women and men were almost without exception definitely neurotic. As regards the preponderating influence of the female sex, it may be that it is really much more common, but it is also possible that it is not so, and that men go about with movable kidneys and do not complain. I suspect, however, that my figures, small though they be, give a pretty accurate idea of the relative frequency of the affection in the two sexes, and the cause of this preponderance may possibly be the prevailing mode of dress in the female. It is needless to say that tight lacing must be a great influence for its production, but tight lacing is not necessary. There are lots of women who would be insulted at the bare suggestion of such a thing, and yet on undressing they have no little difficulty in unfastening their corsets. And if you ask them whether they do not find them tight, they will almost certainly reply that if they had them looser there would be no support. *Support*, therefore, means a very fair amount of constriction of the lower part of the chest, and also a considerable power in extruding the kidney from its snug bed up under the ribs. Thus far there is no explanation of the occurrence of pain; but in these cases the kidney was not only movable, it was painful; and unless the mere displacement of the organ was sufficient to cause the pain by dragging, we must apply to the other fact that I have mentioned to explain it, and I certainly believe it was painful because the patient was neurotic, or, perhaps better, that the displacement causes some slight discomfort or tends towards such a thing, and that in the neurotic this is soon transmuted into an intolerable pain, or leads to an explosion in the shape of a violent renal neuralgia. Either way the important fact to be borne in mind is that it may be there by reason not so much of the local displacement as because of the temperament of the individual. And this is a matter of the greatest importance now that movable kidneys are being treated commonly by the operation for their fixation. It might be surmised on *a priori* grounds that, just as has so often happened in dividing, and even in excising, portions of nerves for neuralgic affections elsewhere, after a period of ease the torment has commenced again, so here. For this reason I have been and am averse to having recourse to this operation except as a *dernier ressort*, and I have seen more than one case that bears this opinion out. Some time ago I saw a patient who had very severe attacks of abdominal neuralgia. They were so bad that she had time after time to be put under the influence of an anæsthetic, and kept under its influence for many hours. She had a movable kidney on one side, and the pain radiated much in the position of the displaced organ. She had a belt made, and it acted fairly well as long as she was in bed; but what belt can compete against the abdominal wall, when it is required of it that it shall hitch up the organ under the ribs? and it failed eventually, as all such appliances do fail, besides proving very uncomfortable. It was ultimately determined to operate, as the pain returned, and life under the circumstances was hardly worth the living. The kidney was stitched into position, and I must admit that for many months she had perfect relief, and became quite a different woman. So being, I came to the conclusion that I was wrong, and that fixing the kidney was, after all, a successful operation. But time has gone along, and now I hear that the pain has returned. It is therefore quite possible that although unquestionably great relief was obtained by the operation in this case, it may yet be that the relief is only such as the neuralgic is likely to obtain from the last new form of treatment, whatever it be, and the more decisive the treatment undergone the more the relief for the time being. I do not, of course, wish to slight the value of operative measures in certain cases—all I wish to convey is that the patients are neuralgics, and that to be a neuralgic indicates a vice of nervous action that no operation can hope to cure; and that since an operation is only treating a symptom, in no sense attacking the disease, these are cases for great deliberation. Our endeavour should be to encourage the patient to make light of her trouble, and, by improving her nervous tone by such means as are available, to enable her to bear, and so to cure, the fundamental condition, and only to operate when patient means have failed.

And here may be said what needs be with reference to uterine and ovarian neuralgiæ. I have said it is a bad day for a man when he first knows he has a heart; it is a ten times worse day for a woman when the pelvic pains to which so many are subject are focussed for her by medical opinion upon uterus or ovary. If there is anything that curdles my blood it is to hear a woman talk of her ovaries

Digitized by Google

as of some intimate acquaintance, and I confess that in this sense I have never been able to subscribe to the Pauline doctrine that "our uncomely parts have more abundant comeliness." One cannot of course suppose (as Sir William Gull used to say of the jejunum that it has no pathology) that organs fulfilling such important functions should have no liability to the aches and pains that all flesh is heir to, or even that they are free from a large measure of disease. We know that it is not so, but there can be no doubt that the ovaries are organs that largely concern themselves with functional disease, and with forms of it, too, that penetrate into the inmost recesses of the patient's being. Do we always remember this at the present day with all the prevalent means of treating disease locally? Do we not sometimes undertake local treatment hazardously, I mean as regards the chances of *real* improvement, because it can be effected with so little risk to life? Is it not too often, "It cannot do any harm, and it may do good." Surgery can happily accomplish now much of what it undertakes; but it needs to remember that it has not yet attained to the enucleation of the neurotic constitution. And when I see, as I have seen, the uterine appendages removed for an apparently incurable neuralgia, I see in the measures adopted not the advance of scientific surgery, as some might suppose, but the abasement of the patient, who has been obliged to yield to the force of circumstances. It is a poor result. Operations of this kind are on a par with some of those upon a painful kidney, or with the destruction of Meckel's ganglion for tic. They may be necessary just as war is necessary. But they are nothing to be proud of; they often leave a lot of "bad blood" behind them, and they are conspicuous for the failure of those higher and more fundamental arts of treatment that should have lifted the patient over this necessity. To criticisms of this kind it is often said: "But the people love to have it so"; and true it is. But for us the thought should ever be: With the kidney gone, the ovaries removed, the Meckel's ganglion destroyed, and the pain returned, what will ye do in the end thereof?

With one other subject only do I propose to trouble you, and I have done. It is one perhaps most dear to the neurotic of any I have named, and, shall I say, most indispensable of all as a shelter to the doctor? I need hardly say that I allude now, in its own right, *to the torpid liver.* Ah! what, indeed, should we doctors do without this sluggard of an organ to *treat?* What would many a patient do without a vital of this kind to nurse and think about? "Well, doctor, it is my liver," falls so commonly on the ear, that blue pill, if we are old-fashioned, or podophyllin, euonymin, &c., if we are sensitive to the breath of the trade winds, comes as an automatic response, which hardly, if at all, stirs our sensorium. How often, I wonder, do we really think outside this groove, and question for the particular individual that is at the moment seeking our aid whether we shall take *his* diagnosis or make our own? I shall venture to maintain to-night that the liver is a much-abused organ, and that there are thousands of people in the *civilised* world—the savage has his knowledge of good and evil to come—who are being physicked for their livers with nothing the matter with them, save a dulled or flabby nervous system. But do not let it be supposed from what I have said that I disbelieve in the existence of a torpid liver. Quite the contrary. But I am trying to shift the responsibility of its supposed crimes on to the back of the real offender. All I am contending for is that the torpidity is not a disease but a symptom, and that in nine cases out of ten, when individuals come complaining of their liver, it is *the individual*, not *it*, that is at fault, and that to make such people really well it is necessary to replenish the spirit that animates *them* and at the same time regulates the blood flow in the inmost recesses of their vitals.

And, for example, a disease that I would shift from the shoulders of the liver to those of the nervous system is one that, of all others perhaps, seems the most unlikely—viz., gall-stones. It has long seemed to me that, although we talk and see much of this disease, we are almost absolutely in ignorance as to why these concretions form. "A sluggish liver forms thick bile" may be sufficient for some minds, but why should the liver be sluggish? It is usually supposed that these concretions form in those of sedentary habits and of stout build. But this is not by any means so, and I assert that it is at least as often that it occurs in the *neurotic*, and in a physique that is the thinnest of the thin. Moreover, I have also been struck with the frequency with which people will tell you that their troubles in this respect first began in connexion with, or after, worry of one kind or another. And when we come to think about it, although it seems at first sight absurd to drag in the nervous system for such a tangible and remote affection as gall-stones, it is far otherwise, for there is nothing more reasonable than the supposition that the nervous energies being at a low ebb, or frittered away in a restless anxiety, the liver, which admittedly must require a large supply of nervous current to enable it to get through its work, is too torpid, its various changes are carried on slowly, and performed badly, the cholesterine that should remain in solution is thrown down, perhaps formed in too great abundance, and thus the stone is set agoing. There is nothing in such a train of reasoning that is anywhere outside unreproachable doctrine, and, in my opinion, nothing that is not highly probable. If this is so, what is the use of stimulating the liver, and although such a practice is endorsed by ages of custom, if we retire into ourselves and think the matter out for ourselves by the light of our experience, can we say for certain that the blue pill, the podophyllin, the salines, the Carlsbad salts, and so on, have accomplished the work that we entrusted to their care? I think that were it so we should know more than we do of the why and the how of the formation of these concretions; whereas, in truth, we know nothing of these two points, and we must fain confess that as yet we have not got behind the most obvious symptom of some disease we are in absolute ignorance of.

And now, gentlemen, I have done. In taking leave of my subject, let me remind you of what has been my aim in these lectures. It was, in giving you a clinical exposition of the common neuroses (and here I must say that my original intention was to have given you many more notes of actual cases, but the large amount of material at my disposal and the exactions of time have prevented), to lay stress on the very certain fact that there are limits to the treatment of this class of diseases by drugs and operation, and that there are many conditions in which the cure must come mainly from within—our function in chief being to call out this dormant power. I wanted to insist, because I am sure at the present day we are too likely to forget, that the highest position we can take is to cure people by advice rather than by drugs: to make the public pay for the use of our brains, and not for so many ounces of physic. Drugs have their own field, but they are our instruments only; of themselves they have no vitality, and a sound common sense—may I say a robust physiology?—has a larger mission even than they in the treatment of disease. There is a time to give drugs, and even to give them with a free hand, but there is equally a time when advice only is needed, and not physic—shall I stop there?—no, when to give drugs is quackery! Yes, there are times when to give medicine is to give *poison*, for it sends the poor patient on a hunt for health which no physic will procure, and it lets slip the opportunity—in the exigencies of human pain and of suffering of all kinds too seldom fit—of pointing the ignorant to a future of Medicine, which both for us and for them is an ideal to be hoped for, to be striven for. I am not one of those who think that if one could conceive of a future for Medicine in which drugs should bear no part that the function of the doctor would be gone. Rather do I hold that as the level of health of a community is permanently raised, so is he emancipated for a sphere of larger use, of still more liberal aims, of nobler purpose. But, Sir, that is a subject for a future Harveian lecturer. For me it must be enough to press the conviction I hold that, the large class of ailments that have formed the subject of these lectures admit of treatment, and ought to be treated with a minimum of drugs; and that if we could but prevail on the neurotic to see this, there is many a one who is now passing a life of aimless and too often hopeless invalidism to whom we might certainly promise in language that many of them know too well:

> "Soon will come the great awaking,
> Soon the rending of the tomb,
> Then the lessening of all shadows,
> And the end of toil and gloom"

But that end is not yet. Will it ever be? I must sorrowfully confess that the prosaic side of life suggests a couplet from another source:

> "But when you see that blessed day
> Then order your ascension robe."

None the less, we still can say, "Come from the four winds O breath, and breathe upon these slain that they may live."

Clinical Lectures
ON
STRICTURE OF THE ŒSOPHAGUS,
WITH FOURTEEN ILLUSTRATIVE CASES, IN FOUR OF WHICH GASTROSTOMY WAS SUCCESSFULLY PERFORMED.

BY DAVID NEWMAN, M.D.,
SURGEON TO THE DEPARTMENT FOR DISEASES OF THE THROAT AND NOSE AT THE ROYAL INFIRMARY, AND ASSISTANT SURGEON TO THE WESTERN INFIRMARY, GLASGOW; PRESIDENT OF THE GLASGOW PATHOLOGICAL AND CLINICAL SOCIETY.

LECTURE III.

GENTLEMEN,—In the preceding two lectures we considered together the etiology, pathology, and general prognosis of those diseases which lead to obstruction to swallowing, and now we have to discuss the methods at our disposal to save the life of the patient, or to alleviate his suffering. The treatment of stricture of the œsophagus must rest upon an exact appreciation of the pathology of the lesion you have to deal with. When the obstruction arises from the contraction of a cicatrix, or from spasm of the muscular fibres, or from a combination of these causes, then you are justified in attempting dilatation. This may be done in five different ways—(1) by gradual dilatation, (2) by forcible dilatation, (3) by the action of tents, (4) by electrolysis, and (5) by internal œsophagotomy. The object the surgeon has in view is to dilate the stricture, and to maintain the lumen of the gullet. It is only in so far as he succeeds in doing this that his treatment can be recommended. Let us now discuss the relative value of the various methods I have just mentioned, and in so doing we must consider the *rationale* of the treatment. When a cicatricial stenosis exists we have a double object in view, first to dilate the stricture, and second to promote absorption of the inflammatory tissue. The passage of bougies does both when properly used. At one of the demonstrations I showed you in Cases 10, 11, and 12 how to pass bougies, and indicated the difficulties you might experience in different cases, so that now I have only to answer the question, What is dilatation, and how should it be employed? It is a mechanical process of stretching the ring of organised inflammatory connective tissue which surrounds the œsophagus, and which occasions the stenosis, and also a means of promoting absorption of the newly formed tissue.

Now we will take a case, one in which the history points to injury and subsequent constriction of the gullet. The patient has considerable difficulty in swallowing, as for example in Case 12. Begin by passing a large-sized bougie, gradually go down the scale until you succeed in getting an instrument through, then retain it for five, ten, or fifteen minutes, according as the patient can allow. Tell him to return in three days. Suppose on the first occasion you succeed in passing a No 6, then on the second visit begin with a No. 5, and follow with a No. 6, 7, and 8 if possible. Simply introduce the smaller sizes, but retain for as long a time as possible the largest bougie passed. Then on the third visit begin with an instrument a size smaller than the largest one passed at the second visit, and so on until a No. 15 or 16 can be introduced with ease. In some instances, as in Cases 10 and 12, the pain and spasm induced by the presence of a bougie are so great that the treatment requires to be discontinued, and the œsophagus allowed perfect rest by giving nourishment entirely by the rectum. During the early attempts the passage of an instrument almost always excites coughing, and stimulates the secretion of mucus and saliva, so that the patient experiences considerable difficulty in retaining the instrument. But if the bougie be well softened in warm water and the patient instructed to throw the head forwards without bending the neck, the secretions will flow from the mouth. After a time he becomes accustomed to the use of instruments, and can retain them for a considerable time. To begin with, the operation should be repeated every third day, and gradually as the lumen of the gullet becomes increased the interval may be prolonged. It must be remembered that the introduction of an instrument of any kind is a source of irritation, and, especially if too large a bougie be forced through, it is apt to cause inflammation of the stricture and spasm. Now this is exactly what we must avoid—no force is to be used, there is no hurry. Every case must be treated according to the individual circumstances. In some rapid progress may be made; in others we must be content with but slight improvement from time to time. Indeed, sometimes the same size of instrument may be required from one day to another. You may ask me, How are we to be guided as regards the size and kind of bougie to employ? If you find, after an instrument has been passed with gentle pressure that it is grasped more tightly for some minutes, and to withdraw it is painful to the patient, then you should not attempt any more that day, because it is evident that the bougie is exciting irritation and inducing spasm of the muscular fibres. To pass a larger size would only do harm. Then as to the kind of instrument. Those which I find most useful are gum elastic bougies of uniform size from end to end, and oval on section. Tapered instruments should never be used, as by their employment the operator cannot judge the amount of force he is employing. The same argument holds good against railway or oversliding bougies. I have discussed the subject of gradual dilatation at length, for I consider it to be the safest and easiest method; the one which should be first used and persevered in until you either penetrate the stricture or are convinced that it is impermeable. Before concluding what I have to say on this subject, allow me once more to draw your attention to the fact that force must never be used in the introduction of an instrument through the stenosis. Force in the treatment of this evil, as in that of many others, is no remedy. It is very difficult for me to tell you how much pressure to employ, but one thing you can understand is that the œsophagus may be of a normal size right up to the opening in the stricture, and that the real difficulty is in finding the orifice. The more difficult this is the less should you desire to use force; for instead of penetrating the stricture, the presumption is that you will cause the point of the instrument to perforate the wall of the gullet. It requires not force, but care and patience, to insinuate the bougie through the small orifice, and this can only be done by systematic use of the instrument, and not by groping at hazard on the chance of entering the tiny opening.

It is now my purpose to discuss with you the treatment which should be adopted in individual cases; and I presume that those brought before you during this session afford us sufficient material for consideration. Some of these permitted of palliative treatment only being employed, while in other instances an operation was deemed justifiable. Let us now consider in detail the treatment employed in the seven cases of malignant disease which you have seen. In four cases (5, 6, 8, and 9) palliative treatment only was employed, while in three cases (3, 4, and 7) gastrostomy was performed. Whatever may be done in these cases, two objects are constantly held in view: to give the patient nourishment in the most convenient way and to alleviate pain. Local treatment is of no avail unless in a few exceptional cases. During the early stages of the disease—that is to say, at a period when the patient is able to take a reasonable amount of food, the diet should be highly nutritive and in no way irritating. The staple articles of diet must be soup, milk, eggs, pounded meat, and farinaceous food. I may now say a word or two as to how these should be prepared. Beef-tea, so-called, and extracts of meat are not so nutritious as is generally believed. At the Royal Infirmary we have a preparation called "composite soup." It is prepared by stewing at a temperature of 200°F. for six hours two pounds of hough meat,[1] one chicken and a knuckle of veal, in two quarts of water without salt. When allowed to stand in a cold place for six hours the fat rises to the surface, and forms a hard cake, while the soup forms a jelly. The fat, if desired, may be removed, and the jelly may be given either cold or heated and taken as soup.

In regard to the use of milk and eggs, the less these are cooked the more easily are they assimilated. If digestion be imperfect, these, as well as other articles of diet, may be artificially digested before they are given to the patient. Patients suffering from stricture find great difficulty in

Digitized by Google

swallowing ordinary bread, as well as other farinaceous food. When loaf bread is masticated it forms a pulpy mass, on account of the gluten which it contains, and for this reason anyone who has difficulty in swallowing complains first of inability to take soft bread or potatoes. But if the starch be freed from the gluten, as is done in the manufacture of Indian corn flour, before the bread is made, the saliva mixes freely with the starch granules, and the morsel, instead of forming a doughy mass, gradually as it were melts away in the mouth and is easily swallowed, even without the patient taking fluid. Indian corn flour, baked into what is known as "snow cake," is easily swallowed, even in advanced cases of stricture of the gullet. The nurse in the ward prepared these very carefully, and some patients who had been unable to swallow loaf bread for weeks took these cakes eagerly.[2] As long as the patient can swallow easily there is no necessity for passing bougies, unless, of course, for diagnostic purposes. When the stricture becomes so narrow as to require the employment of the feeding-tube, the time has certainly arrived to consider the advisability of performing œsophagotomy or gastrostomy. There are, however, some exceptional cases in which a feeding-tube may be of advantage—namely, those in which together with organic stricture the gullet is narrowed by spasm of the muscular fibres immediately on the introduction of any substance into the passage. In these cases the administration of repeated small doses of cocaine before meals gives considerable relief. But if this treatment proves inefficient the patient must be placed under chloroform and food given by a tube. This mode of feeding can necessarily only be continued for a very short time, but sometimes within a few days the tendency to spasm diminishes and artificial feeding is no longer required. The use of the tube in cases where a fistula has formed between the œsophagus and trachea is of very doubtful benefit. In such instances it is much preferable to employ rectal alimentation, with the food properly digested before introduction.

In malignant stricture, the situation of the obstruction having been determined by passing a bougie and the diagnosis completed, instruments should not be passed for the purpose of dilating. But as soon as the passage of fluid food becomes difficult, then a small, soft, flexible tube should be introduced, if possible through the nose, and retained. For the first few days the patient may complain of discomfort, but very soon both the œsophagus and the stomach come to tolerate the presence of the tube, through which he may be fed regularly. It is, however, advisable to withdraw the tube for twelve hours every third night; that is to say, unless there is considerable difficulty experienced in introducing it. I may say, further, it is not necessary that the tube should be introduced into the stomach; all that is required is that it should pass beyond the stricture. The employment of a feeding tube should always be resorted to before any operative interference is contemplated. Dr. Krishaber has strongly advocated the indefinite retention of these instruments, which, he says, may be tolerated by the patient for a very considerable period. In my experience they cannot be borne when kept in continuously; but, if removed for a few hours at short intervals, they may be of great service. In the profession there is doubtless a strong feeling that the patient runs a considerable risk in the passing of tubes for malignant stricture. It is true that hard gum elastic tubes or bougies, carelessly or forcibly used, may lead to very serious consequences; but if soft instruments be employed, and the surgeon bears in mind that it is his duty not to force a passage, but by patient, careful, and gentle manipulation to guide the tube through the stricture, then little is to be feared. In two private cases of malignant stricture I have employed with a satisfactory result a method first proposed by Dr. James Charters Symonds in 1885.[3] When a tube is passed through the mouth or nares it is liable in some instances to cause pharyngeal or laryngeal irritation, and give the patient much distress from his being required constantly to expectorate saliva or mucus during day and night. But by employing the method which I shall presently describe to you these difficulties are to some extent obviated. In place of passing a long tube a short one is substituted, which keeps only the stricture open, and does not cause general irritation of the canal. The idea is to insert a small funnel-shaped tube into the stricture, and to retain it there as long as possible. The method I employed was to pass an ordinary œsophageal bougie and measure the lumen of the stricture. This being determined, I had a soft vulcanite tube made of a proper size, and so shaped that its upper end could be fitted on to the bougie. The funnel-shaped tube was introduced through the stricture on the point of the bougie, the bougie was then withdrawn, and the little tube was left in the stricture. The lower extremity of the small tube was bulbed slightly, with the object of fixing it in position, and to the rim of the upper or expanded end a number of silk threads were attached, which, joined together, formed a cord, and was brought out through the mouth and fixed to the right ear of the patient. In both cases the stricture was kept open for a considerable time, but in the end it was found impossible to introduce those little tubes, and as no bougies could be passed, and neither of the patients would allow gastrostomy to be performed, the usual result of stricture of the gullet followed.

Rupture of cicatricial strictures by forcible dilatation is a method of treatment proposed by some surgeons who have been tempted by the rapidity and facility of gaining their immediate purpose. The results have been less severe than might be expected, although in some instances serious effects have followed. When relief is afforded it is immediate, but unless bougies be passed at regular intervals its duration is brief. The reason of this is very evident. No sooner has the cicatrix been ruptured than it begins to heal, and within a very short time the stenosis is as firm as before the operation was performed. A method I employed in the treatment of stenosis of the larynx is also applicable to stricture of the œsophagus.[4] When it is found impracticable to relieve the cicatricial stricture by gradual dilatation with bougies, I have attempted to slowly stretch the constricted part by inserting a tent made of tupelo wood. A bougie which can be easily passed through the stricture is taken and divided three inches from its point. Between the two divided parts a tupelo wood dilator—the same size as the bougie, and two inches in length—is inserted, and firmly fixed on a copper wire. On the upper end of the wood, where it joins the bougie, a bulb is made of celluloid; so that we have an instrument, the first three inches of which is gum elastic, the following two inches tupelo wood, the upper end of which is covered by a small ball of celluloid, while the remaining part of the instrument is an ordinary bougie. The patient having had the pharynx sprayed with cocaine, and swallowed a little of it, the instrument is introduced until the celluloid bulb rests upon the upper margin of the stricture. The expansion of the tupelo wood takes place by absorption of fluid through its transverse section only. On this account the increase in the bulk of the tent is slow, and the upper end being embedded in celluloid the dilator ultimately assumes the form of a solid cone, and thereby may be easily extracted. Three hours are sufficient time for the tent to expand to twice its original bulk, when it may be withdrawn, and in the course of four or five days a larger size of dilator may be substituted, and so on until the œsophagus is sufficiently distended. This method of treatment is only applicable to cases not dilatable by bougies in the ordinary way. In two cases I have found it of great value. These two cases were previously treated by electrolysis, at a time when this mode of treatment was being advocated for the relief of stricture of the urethra, with the hope that the electrolytic action might gradually produce a softening of the cicatricial tissue. The idea in using electricity in this way is that the current produces increased activity in the tissues, and causes a rapidity of change towards health; but the precise vital or chemical changes produced in electrolysed tissue are still unknown. However, to give the method a trial, I extemporised an œsophageal electrode.

The way to employ this treatment is as follows:—The negative pole of the battery is connected to the œsophageal electrode, whilst the positive is held in the patient's hand, and in order that the exact strength of the current may be estimated a galvanometer must be introduced into the circuit. At the commencement of the sitting the current employed may be equal to five milliampères, and this should be steadily increased to ten milliampères, if the patient does not complain of pain. Ten minutes' application is as much as should be employed at one time, and it may be repeated every fourth or fifth day. Care must be taken that the current be not reversed during the operation, otherwise considerable pain may be occasioned, or even bleeding from the œsophagus. During the time the bougie electrode is in the

œsophagus gentle pressure should be employed, so as to make it traverse the stricture, and as soon as this is done the current may be stopped. My experience of treatment by electrolysis is too small to permit me to confidently express an opinion of its value, but from what I have seen I came to the conclusion that it caused considerable irritation, and probably did more harm than good. So rather than experiment further with patients suffering from œsophageal stenosis, I have been carefully watching the results of the treatment by electrolysis of other more accessible diseases, and as far as I can learn they are not very encouraging.

The last method I will describe to you for relieving the stenosis by an operation from within the gullet is that of internal œsophagotomy. Probably on account of the success which has attended the performance of a similar operation for stricture of the urethra surgeons have been encouraged to divide the obstruction in the gullet by an incision, but the results have been by no means satisfactory. The operation is performed by an œsophagotome, which consists of a gum-elastic bougie, carrying a wire, to the end of which a knife is attached, and by pressing a button, the knife is protruded at will. The curved tube with the knife concealed is passed beyond the stricture, after which the knife is protruded so that it cuts through the stricture on withdrawal of the instrument. In this operation the incision is made from below upwards; in some instances, however, where the œsophagotome could not be passed through the stricture, attempts have been made to divide it from above downwards, but such a procedure is highly dangerous, and should in no instance be practised. The circumstances which call for internal œsophagotomy are very exceptional, and to my mind hardly exist. Although it has been performed for malignant and tubercular diseases, I do not think anyone would, on the chance of gaining temporary relief, submit a patient to the dangers attending the operation. Again, in cicatricial stenosis, internal œsophagotomy can be employed only in cases where a bougie of a good size can still be passed, and therefore in a class of cases in which gradual dilatation with bougies or tents might still be used without risk. When you think of the cases which have been brought under your notice this session, and when I recall those which have come under my observation, I cannot say that I remember a single instance in which I would feel justified in having this operation performed. When the stricture is situated a little above, at, or below the bifurcation of the trachea, the danger of cutting right through the thin œsophagus, and of injuring the trachea and aorta, or of opening into the posterior mediastinum, is very considerable. Of thirty-two cases where this operation was performed which I have inquired into, nineteen were afforded a more or less permanent improvement, nine died from the immediate and four from indirect results of the operation, so giving a mortality of a little over 40 per cent.

Within the last few years another operation has been proposed and practised by Gussenbauer, von Bergmann, and Sands—namely, external œsophagotomy, afterwards dividing the stricture from within, and subsequently allowing the fistula in the neck to heal spontaneously. This operation can only be employed when the stenosis is situated high up; but, on the other hand, when it occupies the lower end of the tube, the stricture has been dilated from below after a preliminary gastrostomy. This operation, said to have been suggested by Schede, has been performed by von Bergmann, Billroth, Studegard, Frittini, Catani, and Loreta, and most of the cases have been successful.

(To be concluded.)

RETRO-PHARYNGEAL ABSCESS IN INFANCY AND ITS TREATMENT.

BY BILTON POLLARD, B.S., F.R.C.S.,
ASSISTANT SURGEON TO UNIVERSITY COLLEGE HOSPITAL AND SURGEON TO THE NORTH-EASTERN HOSPITAL FOR CHILDREN.

RETRO-PHARYNGEAL ABSCESSES were formerly considered to depend invariably on spinal caries. There is no doubt, however, that this was a mistaken view. The majority of cases occur in quite young children, and in them the pus collects in the cellular tissue between the pharynx and the fascia covering the prevertebral muscles; whilst the tubercular abscesses, which depend on spinal caries, are situated beneath the fascia and ligaments, in close contact with the vertebræ. The relative frequency of the two classes of retro-pharyngeal abscess has been pointed out by Bokai, who collected the records of 204 cases which had been observed at the Children's Hospital in Pesth during a period of twenty six years. Only seven cases in this large total were dependent on spinal caries, whilst as many as 189 were of a purely local nature. Judging by the few recorded cases, from the little that is said on the subject in surgical text-books, from my own personal experience and from that of the medical friends whom I have consulted, I am led to think that retro-pharyngeal abscess is a comparatively rare affection in London. At the North-Eastern Hospital for Children, where the number of out-patients (new cases) in the year has ranged between 13,000 and 15,000, I have only met, during the last five years, with three cases, two of which were under my own care, and one under the care of my colleague Mr. Dean. All three cases were acute, and had no connexion whatever with spinal caries. Although not a common disease, acute retro-pharyngeal abscess of infancy merits a wider recognition than it appears to have obtained, for it not only gives rise to serious symptoms at all times; but it may, by bursting suddenly, especially during sleep, cause death by suffocation, although the condition is one which, if detected, may be completely relieved by a simple enough operation. The following four cases derive additional interest from the manner in which, notwithstanding the small size and the tender age of the patients, they were treated.

My first case was a male child aged seven months, who was admitted to the children's ward at University College Hospital on April 10th, 1890, on account of difficulty in breathing. The child had been ill for seven days, at first apparently owing to a nasal catarrh, but during the three or four days previous to admission it had had a "hard and dry" cough, and had had difficulty in both breathing and swallowing. The child was rather rickety. Respiration was accompanied by a snoring sound, chiefly during inspiration, during which also there was slight recession of the ribs and supra-clavicular regions. The child took its food readily, but deglutition was difficult. The back of the tongue was thickly coated, and there was a quantity of thick mucus in the throat. In the notes of the case it is stated that the left tonsil was so much enlarged and reached across to the left side so much that it was almost impossible to get the finger beyond it. No fluctuation was detected. The glands on the left side of the neck below the angle of the jaw were slightly enlarged, whilst in other parts of the body they were not enlarged. The temperature ranged between 98·2° and 100·4° F. On the day after admission an incision was made into the swelling in the throat and a quantity of pus sponged out. Breathing and swallowing were temporarily relieved, but two days later the child's breathing was very difficult and the swelling in the throat had returned. It was incised again, and a large quantity of pus let out, with great relief to the child; but in the course of two or three days the swelling began to form again, the temperature rose, and the breathing became more difficult. I saw the child a week after its admission, and found that the abscess did not involve the tonsil at all. It was situated behind the pharynx, chiefly on the left side. I determined to open it from the neck, according to the plan recommended by Professor Chiene. A small incision was made along the posterior border of the sterno-mastoid, near its upper end, and carried through all the superficial structures till the muscles in the floor of the posterior triangle were reached. The tissues behind the deep vessels and nerves of the neck were then torn through with blunt instruments sufficiently to admit a finger to such a depth that it could be felt by another finger in the pharynx to be close to the outer border of the abscess. A director was then thrust into the abscess, and as soon as pus was seen escaping, the opening was dilated with a pair of dressing forceps, and a tube was inserted. On the following day the swelling in the throat had almost entirely disappeared. Both breathing and swallowing were easy. The temperature was a little raised for four days in association with a patch of pneumonia. A tube of smaller calibre was inserted on the second day. The tube was gradually shortened and completely removed on the ninth day after the operation. The child was discharged a month after the operation, since which it had no difficulty either in breathing or swallowing.

My second case occurred at the North Eastern Hospital.

Digitized by Google

The child was a female, aged thirteen months. She was admitted on April 11th, 1891. For the last three months and a half the child had had a discharge from its left ear. Ten weeks ago the lymphatic glands on the left side of the neck, both in front of and behind the sterno-mastoid muscle, began to enlarge. Eight weeks ago a small abscess burst just below the left angle of the lower jaw, and healed up in about a week. During the last month breathing had been noisy, especially during sleep, from which the child frequently awoke gasping for breath. During the last month also deglutition had been difficult. Liquids were often regurgitated at once. On admission to the hospital the child was pale and flabby, and presented slight signs of rickets. The child breathed fairly well. On examining the pharynx, a swelling was seen on the left side extending from the posterior part of the tonsil to rather beyond the middle line. It reached upwards beyond the soft palate, and its lower limit could only just be felt. The swelling was very tense, but elastic. There were no signs of spinal caries. The abscess was opened externally in the manner described in the last case. The cavity of the abscess was scrubbed out with a piece of sponge and drained by a long tube. The symptoms at once subsided. Respiration and deglutition were henceforth normal. The tube was shortened very slowly in order to avoid re-accumulation. The glandular swellings quickly subsided, and the child was quite well three weeks after the operation, and continued so when last seen three months later.

The third case, a female child aged two years and one month, was admitted to the North-Eastern Hospital on Sept. 14th, 1891. The child had been noticed to be "out of sorts" for about a week. Two days before admission the child began to make a peculiar noise during inspiration, got rather blue in the face, and coughed up a quantity of froth. During the day and night before admission the child had repeated fits of choking. On admission, the child was pale, thin, and weak-looking. Its voice was hoarse; respiration was noisy but not difficult when the child was awake, though during sleep it was distinctly laboured, and the child frequently woke up with a start. The glands in the neck about the angle of the jaw were slightly enlarged. There were no signs of spinal caries. The back of the pharynx was found bulged forwards by a swelling, which on the right side reached to the lateral wall and on the left side to about a quarter of an inch from it. The upper limit of the swelling was on a level with the soft palate, when it was dependent, and the lower limit was opposite the top of the larynx. Fluctuation could be detected in the swelling. The abscess was opened through an incision an inch in length along the posterior border of the sterno-mastoid, about an inch below the mastoid process. The dissection was then carried on with blunt instruments behind the deep vessels and nerves until the swelling was reached. A director was then thrust into the abscess and the opening was enlarged with dressing forceps. About an ounce of pus was let out. The cavity was mopped out with 1 in 500 solution of perchloride of mercury, drained, and dressed with sal alembroth gauze and wool. After the operation the symptoms did not improve—in fact, they got gradually worse. The temperature still ranged between the normal and 101°. On the third day after the operation the child began to get rather cyanosed, and had frequent fits of dyspnœa. She was put in a steam-tent and hot fomentations were applied to her neck. I saw the child again on the fourth day after the operation, and found that the swelling at the back of the pharynx was larger than ever. A steel director was passed in through the wound, and about two ounces of pus were let out. The tube was not lying in the abscess cavity. It was replaced. During these manipulations the child was nearly asphyxiated; but when they were completed she fell asleep immediately, and continued sleeping quietly for the next twelve hours, excepting when she was roused up to take food. There was no further difficulty with breathing. The temperature now fell, and in a few days was normal. On the third day after the second operation the retro-pharyngeal swelling had almost subsided and the voice had almost lost its hoarseness. There was an abundant discharge from the tube, which was slowly shortened, and not left out entirely until the twenty-third day. The child was sent home on the following day, and ten days later she was perfectly well.

The fourth case which has come under my notice was under the care of my colleague Mr. Dean, to whom I am indebted for permission to include it in this paper. The patient was a male child aged seventeen months. She was admitted to the North-Eastern Hospital on Oct. 13th, 1891. Ten days before admission the child had a "general cold." Three days later its breathing was troublesome at night. The difficulty in breathing got gradually worse, and some difficulty in swallowing also came on. The child when admitted to the hospital was suffering with intense dyspnœa. There was marked recession of the chest and the face was livid. The right side of the neck was rather swollen. The posterior wall of the pharynx was very red and tense, and was pushed so far forwards that it almost blocked the fauces. The swelling, in which distinct fluctuation could be detected, extended upwards to the base of the skull and downwards to the top of the larynx, and laterally, on each side, to the posterior pillars of the fauces. The condition of the patient, owing to the obstruction to the respiration, was extremely urgent. Mr. France, the house surgeon, performed intubation with one of O'Dwyer's tubes (suited to a child between two and three years old) quite readily; but, as soon as he removed his finger, the swelling bagged over the end of the tube and blocked it. Respiration had now ceased, and so Mr. France decided, in my opinion wisely, rather than trust to the chance of being able to re-establish respiration, after opening the abscess in the throat, to perform tracheotomy at once. This he did, and, after stimulation and artificial respiration, the child came round and went to sleep, breathing easily through a Parker's tube. It was now about 11.30 A.M. Mr. Dean saw the patient shortly afterwards, and decided not to open the abscess until the child had recovered somewhat from its exhausted state. At 9 P.M. Mr. Dean made an incision three-quarters of an inch in length along the posterior border of the sterno-mastoid muscle and an inch below the mastoid process, and after dividing the fascia beneath the muscle, the pus was quickly reached, and two ounces were evacuated. The abscess cavity was explored with the finger, but no signs of cervical caries were found. The cavity was washed out with 1 in 2000 solution of perchloride of mercury, drained with a large tube, and dressed with boracic fomentations. For two nights and days the child remained in a very restless and exhausted state, but after that time it began to improve. The temperature, which had reached 102·2° F., did not fall to the normal till the fourth day, and the tracheotomy tube could not be left out permanently till the sixth day after the operation. On the twenty-second day the tracheotomy wound had closed, and the tube was left out of the abscess cavity. The child was discharged well three days later.

All the four cases above recorded recovered completely, the abscess cavity closing up quickly. The abscess in each had clearly no relation to spinal caries; it was evidently an entirely local affection. In none of them was the tonsil the seat of the abscess, and, in fact, so far as my observation goes, tonsillar abscess is very rare, if it occurs at all, in such young children as were those whose cases have just been narrated. Two views have been advanced to explain the origin of these acute retro-pharyngeal abscesses which occur in young children. One is that they depend on an acute phlegmonous inflammation induced in a similar manner to acute abscesses elsewhere; and the other is that they are dependent on an adenitis which is secondary to inflammation of one of the neighbouring mucous surfaces. In connexion with the latter view we have an important observation by Dr. Edmund Simon,[1] who describes the lymphatics of the retro-pharyngeal region as forming networks on each side, which terminate in glands located one on each side of the median line between the pharynx and the aponeurosis of the prevertebral muscles. He further states that the glands disappear altogether after the third year of life. In striking agreement with this observation is the fact that the majority of acute retro-pharyngeal abscesses occur in quite young children. The ages of the four cases recorded above were seven months, thirteen months, twenty-five months, and seventeen months. The great majority of Bokai's cases occurred in children under two years of age, and 196 out of his 204 cases occurred under three years. Henoch[2] says that almost all his cases occurred in children still in their first year or little beyond it. In equal agree-

ment with Simon's observation is the fact that the abscess is usually unilaterally placed. This was so in my three cases. The primary inflammation from which the glands are infected may involve the pharynx, the posterior part of the nasal fossæ, the fauces, or the tympanum. In two of the cases above recorded the first sign of illness was a nasal catarrh, and in one an otitis on the same side of the body as the retro-pharyngeal abscess was situated. The disease may come on either very acutely or somewhat insidiously. If the abscess is situated behind the upper part of the pharynx, deglutition will be chiefly embarrassed; but if it be situated lower down, respiration will be also impeded. The difficulty in breathing is especially noticeable during sleep, when, too, it may be accompanied by snoring. The voice, as in one of my cases, may be hoarse, owing to associated laryngeal catarrh. The lymphatic glands on one or both sides of the neck are generally swollen. These symptoms are sufficiently suggestive to lead to an examination of the throat, when if there is a retro-pharyngeal abscess a soft and fluctuating swelling, situated usually rather to one side of the middle line, and bulging the posterior wall of the pharynx forwards, may be felt.

As soon as a retro-pharyngeal abscess is diagnosed steps should be taken to open it, lest urgent dyspnœa come on (as happened in one of the cases recorded in this paper), or in case the abscess burst when the child is asleep or when assistance is not at hand, and the matter be sucked into the larynx and cause suffocation. There are two possible methods of opening the abscess. It may be opened by an incision through the pharyngeal wall or by an external incision in the neck. The first plan is no doubt the most enticing, owing to the ease with which it can be carried out, but it is not free from objection. The abscess cavity cannot be drained with a tube when the opening is into the pharynx, and consequently the incision may close too soon and the pus may reaccumulate. This occurred in my first case; and, indeed, it was this repeated reaccumulation which led me to dissect down from the outside, after the plan recommended by Professor Chiene, notwithstanding the small size and tender age of the patient. Again, proper antiseptic treatment is impossible when the abscess has been opened in the pharynx. If, however, this plan is adopted, the child should be put under the influence of chloroform, the mouth should be gagged open, and the head should hang rather over the end of the table. The abscess should then be opened by a longitudinal incision reaching the entire length of the swelling, and the pus should be rapidly sponged away, so as to prevent any of it finding its way into the larynx.

Professor Chiene's plan of opening chronic retro-pharyngeal abscesses dependent on spinal caries is well known; but I am not aware that it has been adopted for the acute abscesses occurring in infancy, unless the pus was pointing externally. There is, however, no difficulty in performing the operation even when the abscess is small and confined to the retro-pharyngeal tissue, and when the patient is quite a young child. In my first case the abscess was not only strictly retro-pharyngeal, but it had been partially drained into the pharynx, and the child was only seven months old. The operation was done as follows in all the cases. An incision, about an inch in length, and about an inch below the mastoid process, was made along the posterior border of the sterno-mastoid. After the fascia covering the muscles in the floor of the posterior triangle was exposed, a cautious dissection with blunt instruments was made behind the deep vessels and nerves of the neck until one finger placed in the wound almost met another placed in the pharynx. A director, guided by the finger in the pharynx, was then thrust into the abscess, and the opening enlarged by passing a pair of dressing forceps into it and forcibly separating the blades. A drainage-tube should be inserted, and care should be taken that it does not slip out of the abscess cavity, as happened in one of my cases, and give rise to re-accumulation of pus.

THE SMALL-POX AT BATLEY.—The Batley Corporation have now arranged to make considerable addition to the isolation hospital near Howden Clough, the alterations being mainly for convalescent purposes.

ACUTE CATARRH OF THE LARYNX.

BY GORDON HOLMES, M.D.,

PHYSICIAN TO THE MUNICIPAL THROAT AND EAR INFIRMARY, LONDON CONSULTING PHYSICIAN TO THE SHEFFIELD EAR AND THROAT HOSPITAL.

(*Concluded from page 305.*)

Pathological anatomy &c.—In addition to the objective appearances revealed laryngoscopically, the closer inspection to be obtained in the post-mortem room allows the recognition of other changes in the laryngeal mucous membrane. Thus the usual proliferation and shedding of epithelium consequent on inflammation of mucous tissue can be accurately studied. Catarrhal erosions may thus be seen in patches where the epithelium falling away has laid bare the basement membrane. Such erosions may even occur on the free edges of the vocal bands, marring the even outline of the parts, so as to be visible during life with the laryngoscope. According to Krishaber,[1] other ulcers, which he calls "glandular erosions," not larger than a pins' head, may also be present, surrounding the orifices of the mucous follicles. Tumefaction of these mucous glands is also generally present, and when the tissues are put on the stretch by manipulation their openings give exit to a purulent secretion. Distension and rupture of minute veins, producing numerous ecchymosed points, are also commonly to be noted. In some cases the redness of the larynx observed ocularly during life is found to have almost disappeared after death, a phenomenon which is explained, though insufficiently, by cadaveric retraction of the elastic fibres which form so large a part of the mucoid derma. Microscopic examination of the expectorated matters shows the presence of all the elements of epithelial disintegration just spoken of, together with both white and red blood-corpuscles, even when no sanguineous tinge is visible to the naked eye. When the disease is at its height a great part of the mucous discharge consists of pus cells. The source of the pus in inflammation of this kind is still a question of some obscurity. According to Eberth[2] and others it consists of altered cells of cylindrical epithelium; in proof of which they point to their being frequently observed to retain indefinitely the vibratile cilia. Rindfleisch,[3] again, is still inclined to regard the pus cells as for the most part connective-tissue corpuscles, emanating from the body of the mucous membrane, which proliferate and make their way to the surface by the amœboid movements so characteristic of young cells. It seems simpler, however, to accept the well-known doctrine of Cohnheim, who sees in catarrhal pus merely the exudative white blood-corpuscles. As regards the pellets of mucus often brought up, they, as Krishaber[4] suggests, most probably indicate that the catarrh affects the interior of the laryngeal ventricles, where the discharge collects until it attains a certain consistence and volume, and is then extruded by some act of coughing or deglutition.

We have now to consider the suffocative attacks which are often so striking a feature when the affection occurs in children. Here the explanatory statements, which so far have been made, are entirely conjectural. Thus, Niemeyer,[5] after reviewing the circumstances of the accessions, remarks that "it would be natural to admit that a viscid secretion accumulating in the glottis dries there, probably agglutinates the edges of the vocal bands, and thus gives rise to the attacks of dyspnœa." Mackenzie[6] also adopts this view, though without referring to Niemeyer as its prior exponent. Krishaber,[7] again, seeks the cause in "the very slight development of the cartilaginous glottis in children," which renders the glottic chink very narrow. Hence the inflammatory stenosis, though of comparatively minor degree, is able to occasion such urgent symptoms, when aided by "the relaxation of respiratory action which occurs during sleep." Neither of these hypotheses seems to me to take us very far on the path of elucidation, and the

Digitized by Google

more closely they are considered the more unsatisfactory do they become. Why, let us ask, should mucus become so readily inspissated in this malady, which often runs its course without any obvious increase of such discharge, and not in those affections where mucus accumulating near the glottis is a constant feature? If the expectoration tended to block the breath-way, would not, as in these other cases, an expulsive effort be immediately excited, and the passage be cleared without the production of any urgent symptom whatever? Again, can anyone believe in this swelling of the glottis, which becomes so potent an agent for harm during sleep, but in waking moments often does not betray its presence by any physical sign? And is it likely in any case that sleep would be prolonged until the patient had become nearly asphyxiated from obstruction of the glottis? Is not, in fact, respiration as active and as compulsory during sleep as at any other time, when regard is paid to the quiescent state of the body? Is it not better, then, to put aside such recondite theories in favour of some simpler explanation based on the commonly recognised peculiarities of the nervo-muscular apparatus of the larynx? Thus the laryngeal muscles have the "trick," as we may call it, of succumbing to paresis, paralysis, and spasm of a temporary, even momentary, character not paralleled in any other part of the body. Hence even in adult males we may see phonation at one instant impossible, and at the next perfectly re-established on the application of the slightest stimulus to the vocal region. In adults, spasm of the glottis is also commonly excited by any trifling irritation of the laryngeal vestibule &c. Chronic cases of such spasm, occurring on awakening towards morning, are also tolerably frequent, and I have met with several instances in men of mature age who were in other respects apparently sound and healthy. With such data, combined with the well-known proclivity of children of tender years to suffer from reflex spasm, and the more delicate sensibility of the laryngeal mucous membrane among other internal parts, have we not sufficient grounds to attribute the phenomena we are treating of to a passing neurosis of the muscles of the larynx—chiefly, or perhaps entirely, a spasm of the constrictors of the glottis? Possibly even the peculiar vulnerability, firmly believed in by some authorities, of the abductors of the vocal bands produces an abeyance of their function, which facilitates the occurrence of glottic stenosis from any concomitant cause. I have, indeed, already reported two instances of abductor paralysis[8] in which the malady appeared as the sequence of acute catarrh of the larynx. Both Ziemssen[9] and Gerhardt[10] also attach great weight to disturbances of innervation as explaining the phenomena of this malady, over and above the mechanical interferences with function arising from mere alterations of form and substance. Hence alterations of tension, consonant action, &c., of the vocal musculi may modify both voice and respiration.

Diagnosis.—Acute catarrh of the larynx is easily recognised, either from the patient's description of his sensations or from inspection with the laryngeal mirror. The very limited extent to which cough and expectoration are present serves to distinguish it from ordinary catarrhs of the trachea and bronchi—the absence of chest symptoms from the graver inflammations affecting the lungs. The general mildness of the phenomena, both local and constitutional, will not allow it to be mistaken for any serious laryngeal disease, such as œdema or diphtheria. In childhood the practitioner is little likely to confound it with genuine croup on account of the suddenness of the accession of dyspnœa and its evanescent character. Nor is he likely to be misled by the so-called "croupy" cough, which with its resonant ringing timbre is, in fact, the very opposite to the stifled cough which proceeds from the larynx when all its parts are muffled by the exudative membrane. At a later stage of laryngeal diphtheria, when convalescence begins, it may be noted that there is some similarity of cough tone between the two maladies, so that, as Trousseau[11] remarks, it may be said that "false croup begins where true croup ends." With respect to laryngismus stridulus an error is not likely to occur, as the spasmodic attacks are usually much less urgent, and the malady has generally been persistent for some time before medical aid is appealed to. The peculiar crowing inspiration, as part of a general convulsive tendency, has also a much more signal character than that which is observed in the merely catarrhal affection. There is one occurrence, however, peculiar to early life which may create difficulty in diagnosis—viz., the sudden presence nocturnally of a foreign body in the glottis. In children a very urgent, and even fatal, dyspnœa may arise from this cause in the middle of the night, as it is not uncommon for them to go to sleep whilst affectionately preserving some small toy in the mouth. If the article slips down the throat it is very likely to enter the glottis, producing a sudden obstruction to respiration. Such dyspnœa does not pass off like that attendant on the catarrhal lesion, and the observer who is alive to the possibility of such an accident will soon fathom the truth.

Prognosis.—In uncomplicated cases in adults no danger whatever to life is to be apprehended from this malady, which is essentially a laryngitis of minor intensity and short duration. It is never the primary cause of death, and a fatal result can only occur as the consequence of one of those other maladies, general or of the respiratory tract, with which it is sometimes associated. It is not likely to pass into œdema of the larynx, though in persons of a certain constitution it may seem to do so, having really been œdematous from the first. In children the prospects are almost as favourable, but it must not be forgotten that some deaths have been attributed to this disease by practitioners not likely to have been mistaken—notably by Millar,[12] Trousseau,[13] Vieusseux, Wichmann, and Lobstein.[14] Nevertheless Guersant[15] and Bretonneau,[16] although attending specially to diseases of children, never met with one. It may be concluded, indeed, that unless the patient is debilitated by dyscrasia or previous illness recovery is as certain as in adults. In all laryngeal affections the prognosis must be considered with reference to function, as well as to life or health, and especially when we have to deal with patients whose voice constitutes their professional armamentarium. In this department our anticipations cannot be quite so favourable, for we can never tell what persistent weakness of muscle or membrane may follow an attack of acute laryngeal catarrh, the more so as excessive vocal efforts may be the exciting or a predisposing cause of the disease. In such instances the first manifestation may be the forerunner of many similar ones, recurring periodically; while in the intervals a state of chronic catarrh, more or less pronounced, is the rule and not the exception. The practitioner, therefore, can never promise a complete regain of vocal power to patients of this class, although such a result may be hoped for when the attack is clearly of fortuitous origin.

Treatment.—In mild cases in adults the use of steam inhalations, medicated or simple, together with ordinary dietetic and hygienic precautions, persevered in for a few days, will be all that is required to promote a cure. Absolute confinement to the house is not even necessary if the weather be fine and not too cold; but if the patient ventures out a respirator of some kind had better be worn, unless he can be trusted to breathe only through the nose. In the more intense cases the patient must keep to one room, or even to bed, whilst warm poultices or a wet compress are applied to the front of the neck. Mackenzie[17] refers with approval to a German custom of setting the patient to eat salt (red) herrings, the saline constituents of which may doubtless have some curative potency. At the same time restriction to a light diet, chiefly composed of nutrient fluids, and slight purging will materially assist the occurrence of resolution. In the earlier stages sucking ice may also be recommended with advantage. When the active symptoms have passed off the complete restoration of the larynx to a normal condition can be best obtained by the direct applications of astringent solutions with a laryngeal brush. Perchloride of iron (forty grains to the ounce) and chloride of zinc (thirty grains to the ounce) are best adapted for the purpose. When there is hæmorrhage from the larynx the quantity is usually so small that no especial measures are demanded; the discharge, in fact, if allowed to continue is most likely to be beneficial. In those rare instances in which it is considerable and persistent the solution of iron, doubled in strength if necessary, can be applied. In

those examples where the patient is liable to periodical attacks I have been most successful when commencing the treatment with a local application of silver nitrate (from forty to sixty grains to the ounce) combined with the use of the wet compress. In all instances the patient should be enjoined to rest the larynx by refraining as much as possible from coughing or speaking. In children somewhat different measures must be adopted, and even slight cases should be confined to one room and be carefully watched. At the outset an emetic of ipecacuanha and a mild aperient had best be administered. Warm poultices, and perhaps sinapisms, should be applied to the front of the neck and chest, especially during the night. It is also advisable to keep the air of the apartment moist by the use of one or more steam-kettles. An accession of dyspnœa is best combated by fomenting the front of the neck and chest with a large, soft sponge wrung out of warm water. It should be passed with active pressure from side to side, and when cooled redipped in the water. The application of blistering fluid, though commonly resorted to in such cases, had better be avoided. Its action is neither immediate nor far reaching; whilst by making the parts sore it hampers or precludes the after or simultaneous use of more effective measures. Should the dyspnœa be sufficiently urgent tracheotomy must be performed without delay, and though there is, perhaps, no recorded instance [18] of its having been resorted to in an uncomplicated case of the kind, the few fatal examples published indicate that had it been put in practice the number might have been even less.

Finsbury-square, E.C.

RECURRENT APPENDICITIS, WITH REPORT OF CASE TREATED BY REMOVAL OF APPENDIX.

BY MAYO ROBSON, F.R.C.S.,

PROFESSOR OF SURGERY IN THE YORKSHIRE COLLEGE, AND HON. SURGEON TO THE LEEDS GENERAL INFIRMARY.

ALTHOUGH the word "appendicitis" has been objected to by several English writers of authority, "inflammation of the vermiform appendix" seems to be the proper term under which to discuss the form of peritonitis which so frequently occurs in the region of the cæcum, and more extended experience, clinical, operative, and post mortem, leads one to see that the course of the trouble is nearly always in the appendix. The names "typhlitis," "perityphlitis," "paratyphlitis," and "appendicitis," so far as treatment is concerned, may all be considered as forms of peritonitis occurring in the region of the caput coli; and although some of the cases may be due to stercoral or other forms of ulceration in the cæcum, by far the greater number have their origin in the vermiform appendix. Undoubtedly many of the milder forms of appendicitis resolve under medical treatment; and even when pus has formed, in quite a number of cases it makes its way to the surface and bursts through the abdominal wall, or is evacuated by other channels; but as one can never say that it may not burst into the peritoneal cavity, and as Dr. Bull has shown that in 12 per cent. of the cases in which suppuration has occurred this accident does happen, it is easily understood how those who realise the dangers of the disease should advocate early surgical interference. A convenient method of classification of pericæcal inflammations is that proposed by Prof. With of Copenhagen, who describes: (1) An adhesive local peritonitis, caused by ulceration in the appendix and clearing up without suppuration; (2) a local peritonitis, ending in abscess; and (3) diffuse peritonitis, either caused by perforation of the appendix before adhesions have formed, or by secondary rupture of the well-developed abscess. To make the classification complete, to these would have to be added a fourth form, relapsing typhlitis, described by Mr. F. Treves, of which the case here related is an example. But it seems to me that instead of making these four divisions two will suffice: (1) Appendicitis without suppuration, dependent on ulceration or catarrh, and producing local peritonitis, which has a tendency to resolution, but which is also liable to recur; and (2) perforating appendicitis, ending in suppuration and producing either a local abscess or diffuse peritonitis. This, I believe, is a similar classification to that proposed by Dr. Bull, but I think he does not include the recurrent form in his first division.

The following case, diagnosed as relapsing appendicitis and sent to me by Dr. Griffith for operation, is a good illustration of its class. He has been kind enough to include the history in the following letter:—

"DEAR MR. ROBSON,—I am sorry to find that I have mislaid the notes of Miss F——, the case of appendicitis in which you operated last January. She was under my observation about twelve months. When I saw her first she had the ordinary symptoms of what is usually called perityphlitis—viz., rise of temperature, constipation, pain in the right iliac region with great tenderness on pressure, and on careful palpation one could make out a mass of considerable size in this position. The attack passed through an ordinary course, and the swelling slowly disappeared, though I could never satisfy myself that it disappeared entirely. From the time of this attack until you operated on her she had had about six or seven attacks, some severe, others milder, but all attended with rise of temperature and tenderness. The first attack she had was said to follow on a strain, and she says she had some six or eight attacks prior to my seeing her the first time. As the attacks were getting milder, I did not at once urge operation; but the frequent repetition of attacks, each of which was attended with some danger, led me to suggest that something should be done. Since the operation in January she has been constantly under my observation. 1. She has not had any recurrence of inflammation. 2. She has had some uneasiness about the part; but this seems to be due to some bulging of the cicatrix. 3. The pain in the head she now has is an old symptom, and quite unconnected in my mind with the abdominal condition.—I am, yours very truly,

"T. WARDROP GRIFFITH."

For the following notes of the case I have to thank my late house surgeon, Mr. B. Hall:—"On admission of M. F——, aged twenty, on Jan. 8th, 1891, there was marked rigidity of the abdominal muscles on the right side, especially over the iliac fossa. By distracting the attention of the patient they might be made to relax to a slight degree, when a hard resistent, ill-defined swelling, giving the impression of fulness and thickening rather than of a tumour, could be felt on palpation over the cæcum. As soon as the swelling was touched the muscles became immediately rigid again, and some slight pain was experienced. McBurney's symptom was present. Rectal examination gave no information. The bowels were constipated, but the temperature was normal, and otherwise she felt tolerably well, as she usually was between the attacks. On Jan. 19th, after the bowels had been cleared by an aperient and the abdominal wall aseptic ised, the A.C.E. anæsthetic was administered, and an incision of four inches was made vertically over the cæcum. On opening the peritoneum, the omentum, cæcum, vermiform appendix, and adjoining coils of intestine were found to be matted together, but the adhesions were separated by digital manipulation without much difficulty. The vermiform appendix, which was very much thickened, was found on the inner side of the cæcum. It was without much difficulty separated from its adhesions, when it was discovered that there was a constriction about a quarter of an inch from the cæcum, and that beyond this the tube was dilated and contained fluid, which was afterwards found to be muco-purulent. The appendix had a distinct mesentery, and through this, opposite the point of constriction, a needle armed with a thin silk ligature was passed. This was tightened, and the appendix beyond was cut away, leaving a portion of its mesentery, which was sutured over the cut stump, after the redundant mucous membrane had been removed and the cut surface had been purified by a 1 in 500 solution of perchloride of mercury. No drainage-tube was found necessary. The abdomen was then closed by three layers of sutures, peritoneum to peritoneum, aponeurosis to aponeurosis, and skin to skin. The patient had neither pain nor abnormal temperature after the operation, and made an uninterrupted recovery. The bowels acted on the sixth day, the sutures were removed on the eighth, and the patient returned to her home on Feb. 21st. When last seen, in October, she had had no return of the attacks, and the region of the cæcum was entirely free from any trace of the former tumour; but, through her not having worn

[18] See, however, Dumontpallier's case, reported by Trousseau, op. cit., p. 523.

Digitized by Google

any support after leaving the hospital, the cicatrix had given way at one point and a small hernia had developed, which, however, could be easily retained by a pad and belt."

In such cases there are clearly three courses of treatment open. 1st. Non-operative, trusting to rest, opium, and diet to bring about resolution, in the hope that the existing attack may be the last 2nd. Operation between the attacks, as suggested and first performed by Mr. F. Treves. 3rd. Operation on the second or third day of a seizure, as advised by Dr. F. S. Dennis, who discourages the removal of the appendix between the attacks, arguing that in the great majority of cases the disease does not recur, and that should it do so, removal at an early stage of the attack is both safe and efficient. Before deciding on any definite line of treatment, the mortality of operative measures must be weighed against the dangers of delay. In this case the attacks had recurred so frequently that little hope could be held out to the patient of cure without operation, and, as the removed appendix shows, the seizures would in all probability have been repeated either until an abscess had formed or until perforation had occurred. In discussing a comparatively new operation, statistical evidence is often wanting; but so far as I am able to ascertain, close on thirty operations have been performed for the removal of the appendix during the quiescent stage of chronic relapsing appendicitis, and out of this number only one patient has died.

I question whether the statistics of expectant treatment would yield nearly so excellent a result. The nearest approach to a statistical estimate is a report by Fitz, who estimated the mortality of perityphlitis medically treated at 11 per cent. Laparotomy in the early stage of acute attacks would, I feel sure, show a much larger mortality than operations undertaken when the disease is quiescent. A point of interest in the case related was the marked tenderness on pressure about two inches internal to the right anterior superior spine of the ilium, which was pointed out as an almost positive sign of appendicitis by Dr. McBurney, and which observation I can confirm by having found it universally present in all the cases of appendicitis which I have seen. It would be interesting to discuss the question of operative treatment in the forms of appendicitis ending in abscess or in general peritonitis, in which cases I am distinctly of opinion that early operation is called for, but this is beyond the scope of the present paper.

Leeds.

THE MECHANISM OF DELIVERY OF THE FŒTAL HEAD IN VERTEX PRESENTATIONS; ALSO THE PERINEUM IN LABOUR AND ITS MANAGEMENT.

By J. H. E. BROCK, M.D., D.P.H., B.S. LOND., F.R.C.S.,

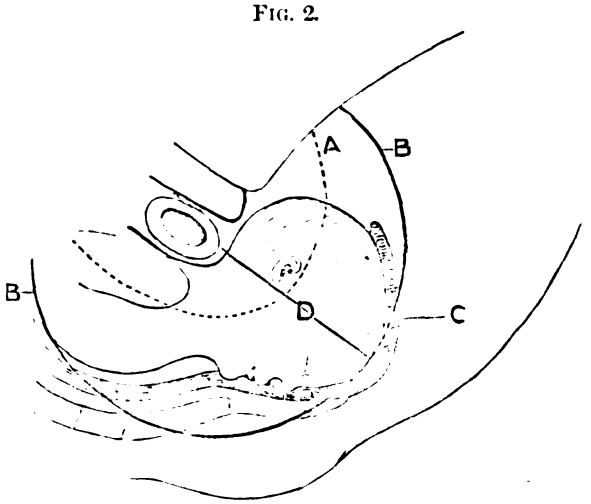
HONORARY PHYSICIAN TO THE WESTMINSTER GENERAL DISPENSARY; LATE RESIDENT OBSTETRIC ASSISTANT, UNIVERSITY COLLEGE HOSPITAL, LONDON.

(*Concluded from page 309.*)

Extension.—Having rotated into the conjugate diameter of the bony outlet, the head in occipito-anterior presentations is described as being born by a movement of extension. Thus, it is said,[1] "flexion continues until the occiput engages between the pubic rami. When the anterior bony wall is no longer encountered, the surface of the child's head glides forwards upon the perineum as upon an inclined plane, and describes a circle beneath the pubic arch, of which the suboccipito-bregmatic[2] diameter forms the radius. The extension of the head, which is an essential feature of the foregoing movement, is the resultant of two forces, derived, first from the uterus, and secondly from the pelvic floor. The uterine action is transmitted in the axis of the superior strait. With the occiput fixed beneath the pubic arch, and the neck resting against the inner surface of the pubes, the propulsive force is expended upon the frontal extremity of the head, and this causes the separation of the chin from the thorax."

Let us examine these statements critically. "Flexion continues until the occiput engages between the pubic rami." This admits of being fairly tested with the fœtal skull on the dry pelvis. On passing the skull in an attitude of flexion through the pelvis, it will be found that as the tip of the occiput emerges from beneath the pubic arch, the anterior fontanelle is against the extremity of the coccyx, a result which would naturally be expected, seeing that the conjugate at the outlet measures only 3¾ in. At this point, then, extension is quite out of the question. On continuing to put the head through the pelvis, it will be found that the chin cannot be made to sweep the coccyx by extension until the occiput has escaped beyond the inferior curved line, and is resting against the pubic arch, just above the foramen magnum. Now, if it be true of the dry specimen, not merely that extension cannot occur as soon as the occiput engages the pubic rami, but that it cannot take place until the greater part of the head has passed through the outlet, it must be still more true in the case of the living body, where not only are the diameters of the fœtal skull somewhat larger, but the pelvic diameters rather smaller, owing to the pubic arch being occupied by the subpubic ligament, the triangular ligament of the urethra, and the vestibule, which would prevent the occiput from being so closely applied to the pubes as in the above experiment. It is of manifest importance, looking to the fact that the conjugate at the outlet measures only three inches and three-quarters, that the diameters of the fœtal head which will engage at the outlet should be kept as short as possible—a result which can only be attained by preserving flexion. The outlet being the narrowest part of the pelvis that the head has to pass through, it is hardly likely that it would accomplish the journey in a state of such disadvantage as extension. Moreover, if extension occurred during the passage of the outlet, soon after the occiput had begun to engage the pubic arch, the top of the head ought to come down and bulge the perineum. As a matter of fact, it will be found that if an examination be made at this point the anterior fontanelle is so high that it cannot be reached, while between the vertex and back of the vagina there is a considerable interval. It is only when a good portion of the occiput has passed through the pubic rami that enough of the head has got on to the perineum to distend it, evidence which points to the head being still in a state of flexion.

While I do not believe that flexion is undone at the bony outlet, I am far from believing that delivery through the vulva is effected by extension. In the quotation which I have inserted above, it will be noted that extension at the vulva is said to be the resultant of two forces—viz., the uterus and the pelvic floor. It is claimed by the advocates of this theory that the occiput having become fixed beneath the pubic arch, "the propulsive force is expended upon the frontal extremity of the head, and this causes separation of the chin from the thorax." This statement supposes the uterus to be capable of influencing directly the movements of the fœtal head so far away as at the vulva. But what are the conditions which actually obtain? So long as the head is contained within the bag of membranes, or has not passed through the cervix, its movements are capable of being influenced either by the pressure of the amniotic fluid or by the direct action of the uterine wall. The head once through the cervix, the uterus by its contractions not only squeezes the fœtus through the pelvis and out of itself, but in so doing adapts itself by retraction upwards to the portion of fœtus still remaining in it, until at the time that the head is being born, it forms a cap over the breech or upper pole. It is evident that under the gradually changing relations of fœtus and uterus the latter becomes in the end reduced to a merely driving force. No doubt the force which the uterus applies to the upper pole is transmitted along the trunk; but it is equally certain that the intensity of this force must die away as the head is approached, and when it reaches the latter be comparatively feeble. We may take it that the force is transmitted along the vertebral column to the head, which it reaches by passing through the occipital condyles. Extension of the head means that the extending force must act on the chin, or, in other words, that the uterus must possess the power of voluntarily changing the direction along which the pressure that it applies to the child is transmitted. It is difficult to see how mere arrest of the occiput at the pubic arch is going to secure this desirable end. Bearing in mind, also, the fact that at the time the head is coming through the



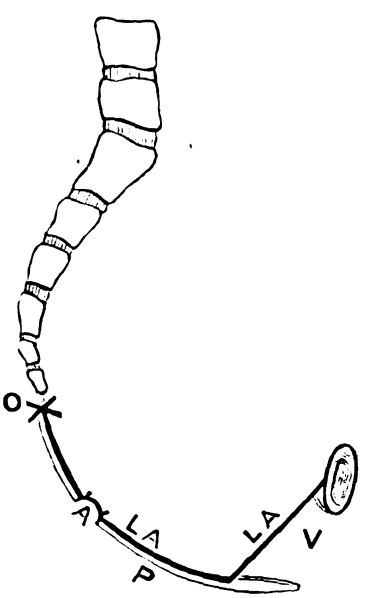
[1] Lusk, pp. 175, 176.

[2] I presume suboccipito-frontal is intended, and not bregmatic.

Digitized by Google

vulva the cavity of the pelvis is filled with the thorax and arms of the fœtus, it would be interesting to note the path by which the propulsive force of the uterus picks its way through, and, safely alighting on the chin, tilts it up. There is still another objection to birth by extension. It is the danger with which such a process would be fraught to the mother. After the head has escaped from the bony outlet the perineum becomes stretched and distended in such a manner that the vulva, from looking downwards and very slightly forwards, is carried almost directly forwards. Now, supposing the occiput to have become fixed at the pubic arch and the head to be born by extension, it is evident that in so doing it would describe an arc lying in a plane which would cut the plane of the perineum about its middle at an acute angle, and would thereby execute a movement eminently suitable for splitting the perineum—a

FIG. 2.



The head passing the vulva. A, The axis of the pelvis. B, The arc which the head would describe in executing the movement of extension. C, The perineum. D, The occipito-frontal diameter, or radius of rotation.

result which, considering that labour is a physiological phenomenon, nature would probably take means to avoid if possible.

I have now stated my own objections against the belief that the head is born by extension. I will next point out that although extension is constantly described in theory as occurring at the outlet, obstetricians have in practice been most assiduous in devising methods to prevent it. For this purpose I quote the following "methods," which have been advocated for the "support" of the perineum:—1. "The thumb is applied anteriorly to the occiput, and the index and middle fingers posteriorly to that portion of the head which lies nearest to the commissure, and pressure is exercised in the direction of the vagina" (Hohl). 2. "Pressure is made on the forehead and face with the tips of the fingers on the perineum behind the anus, close to the extremity of the coccyx" (Ritgen). 3. "Pass two fingers into the rectum, and press the face upwards and forwards" (Ahlfeld). 4. "Seize the head between the index and middle fingers of the right hand applied to the occiput, and thrust the thumb as far as possible into the rectum" (Fasbender). 5. "The physician, standing to the right of the patient, with his face towards the foot of the bed, should pass the left hand between her thighs and press the head upwards and inwards during each pain with the thumb and two fingers, as previously described (i.e., Hohl's method). At the same time the movement of extension, should it threaten danger to the parts, should be hindered by pressing backward upon the frontal region through the perineum with the disengaged hand" (Lusk). Clearly the principle on which each one of these methods is based is maintenance of flexion during the passage of the vulva. Indeed, Dr. Lusk goes so far as to be alarmed lest the movement of extension prove a positive danger to the mother. Either, then, art has devised a better plan for the delivery of the fœtal head than that followed by nature, or else while imagining that we have been improving on nature we have, after all, only been following her. The idea that the head is born by a movement of extension rests upon the belief that the occiput becomes fixed under the pubic arch. I have never been able to verify this statement. On the contrary, I have found that the occiput is constantly progressive, and that just in proportion as it emerges from beneath the pubic arch so do more and more of the forehead and face come into view. In other words, the whole head rotates round the symphysis pubis in a flexed position, so that by the time the chin is born the occiput and nape of the neck are projecting beyond the vulva. The perineum forms a sliding floor, by which the curved axis of the pelvis is continued onwards and the outlet of the vagina carried forwards. Owing to these conditions the occiput has only to revolve round the symphysis pubis, while the forehead and face travel along the wide sweep presented by the concavity of the perineum—a movement which might easily be (and I believe has been) mistaken for extension. Moreover, it will be found that as the head is coming through the vulva the lower margin of the vestibule, and other soft structures filling in the pubic arch, form a strong, sharply defined band over the back of the occiput, and constitute the natural means for pressing the occiput down and preventing it from being tilted up towards the pubes.

The perineum.—The management of the perineum during the transit of the head into the world has been, and still is, a much debated question. I have already quoted five methods which have been advocated for the purpose, and might quote a good many more, but forbear. Of the five methods detailed, the interesting point which I have alluded to is that the principle of one and all of them consists in the maintenance of flexion of the head. Holding the view that flexion is the normal position for the head to be delivered in, I freely admit that the principle is an important one. On the other hand, while stating what attention should be paid to the head, none of these methods take any direct account of the perineum itself. But is the perineum deserving of such consideration? I venture to think that a study of the relations of the perineum will repay the inquirer, and while throwing light upon its action in labour, will also afford the key to its rational treatment. Until the head

FIG. 3.

The perineum. L. A, The levator ani. A, Anus. V, The vulva. O, The point at which pressure should be applied in labour.

descends to the outlet the perineum forms a comparatively insignificant structure; but no sooner does the head begin to pass the bony pelvis than it becomes enormously distended, until at the moment that the head is about to traverse the vulva it forms a bed nearly large enough to completely cover the head, and has carried the orifice of the vagina from looking downwards and slightly forwards to a position pointing almost directly forwards. Is this complete transformation in its relations due simply to stretching

Digitized by Google

by the head, or is it materially assisted by some other structure in relation to the perineum? It appears to me that there is a powerful agent besides the head, which has literally been pressed into the service, the action of which, in formulating any plan for the management of the perineum, ought to be carefully kept in view. This agent I believe to be the levator ani muscle. This muscle arises on each side from the back of the symphysis pubis and white line, and, running downwards and backwards by the side of the bladder and vagina, is inserted into the perineum from the central point backwards to the coccyx. The effect which these muscles would exert upon the perineum is evident. With the head pressing backwards upon the rectum, both muscles, and particularly their anterior portions, inserted in front of the rectum, would be put upon the stretch, and by their traction would tend to pull the front of the perineum forwards. In fact the perineum may not inaptly be compared to a hammock, having its attachments behind to the sacrum and hips, while the ropes slinging it above and in front to the pubes are the levatores ani muscles. It will further be noted that a peculiarity of the perineal hammock is that the anterior ropes are not tied to its front only, but are fixed along the whole bed up to the central point, while all between the latter and the vagina is free. The effect of these peculiar attachments is plain. The front of the perineum, immediately adjacent to the vulva, is left free and untrammelled—an obvious advantage, as it is the part which will have to be stretched to allow the head to come through. On the other hand, the portion behind, while much strengthened on its sides by muscle, is weakened along the middle line of its floor, this being the line along which the levatores ani are attached, and which is subjected to the greatest amount of traction. It is along this line that the perineum splits. Granting this view to be a correct one, the principles which should be kept in view are—1. Interfere with the natural tendency of the perineum to be pulled forwards as little as possible. 2. Leave the front of the perineum quite unfettered, to dilate as freely as its structure will admit. 3. Take off the tension from the middle line, along the insertion of the levatores ani muscles. All these requirements are completely fulfilled, together with that fourth and very important one, maintenance of flexion of the fœtal head, by pressure applied just in front of the coccyx in an upward and forward direction. By so doing the perineum is helped forward, the tension of the levatores ani upon the floor of the perineum is relieved, the head is kept flexed and closely applied to the pubes, while the anterior part of the perineum is left free to dilate. The plan I have found most convenient is to apply pressure with the thumb of the right hand, the fingers being free to control the passage of the head through the vulva, should it be deemed desirable to delay the birth till more complete dilatation has taken place. The results which I have obtained by a practical application of these principles to fifty cases of vertex labour at full term are: Forty-three multiparas, two tears; seven primiparas, one tear. Of the three tears, none of them were serious. One was lateral, through the hinder part of the left labium, and one occurred during the birth of the abdomen. The tear in the primipara was half an inch long and only skin deep, the septum remaining intact. It needed only a single catgut stitch to bring it together.

To sum up, the conclusions which I would venture to put forward are:—1. That rotation is not the result of the inclined planes of the pubes and ischial spines, but of the narrowing of the transverse diameter towards the outlet due to the inward, downward, and backward slope of the pelvic floor. 2. That the head in occipito-anterior presentations is born, not by extension, but in a state of flexion. 3. That the perineum is best preserved by a method which maintains flexion of the head, relieves the tension along its floor, and interferes as little as possible with its normal action in labour.

Adelaide-road, N.W.

THE FULHAM MORTUARY.—A member of the Fulham Vestry, at a recent meeting of the Sanitary Committee, described from his own personal observation a revolting state of things at the Fulham Mortuary, which drew forth strong animadversion from the meeting. Ultimately a subcommittee was appointed to visit the mortuary, accompanied by the medical officer, and report the steps necessary to be taken for its better equipment and management.

NOTE OF A CASE OF TUMOUR OF THE BRAIN THE RESULT OF AN APOPLEXY.

BY J. A. CAMPBELL, M.D.

WITH REPORT OF THE STRUCTURE OF THE TUMOUR BY JOSEPH COATS, M.D.

W. M——, aged thirty-three, was admitted into the Carlisle Asylum on Nov. 17th, 1870. He had not been considered well in mind for six years; when a child he had had fits. Though none of his near relatives had been in an asylum, some of them had been very peculiar. Previous to his admission he had been dull and morose, wishing himself dead, and threatening to injure his father.

On admission he was found to have a good memory, to speak coherently, to reply to questions correctly; but he was in a state of very considerable depression, as shown by his appearance, attitude, manner, conduct, and remarks. A careful note was made of his bodily condition, but I need merely quote that he was a dark-complexioned man of 5 ft. 11 in. in height, and 167 lb. in weight. His temperature and pulse were both slightly above normal, but no disease was detected in his various organs. For some time he was returned as being dull and taciturn, seldom conversing with others and always very peculiar in his conduct and habits, never wishing to leave the place, and on the whole industrious and in good health. For nine years he continued in this state, but in October, 1879, he complained of rheumatic pains for a short time. Only once or twice during this period did he show real signs of being dangerous to others, on one occasion attacking a fellow-patient with a spade. Both attendants and fellow-patients thoroughly recognised that he was not a man to be trifled with, so that for the most part he got his own way, and therefore behaved quietly. In October, 1886, after sixteen years' residence, physical examination shewed no indications of disease, except that the respiratory murmur over the right apex was harsher than over the left. His heart was carefully examined, and nothing abnormal was detected about it. In January, 1891, he did not look quite so well as usual, and was therefore allowed one pint of porter daily, but at this time he was 17 lb. heavier than when he came in. On July 3rd he had a paralytic seizure, with slight loss of power on his right side. He complained of a feeling of giddiness, but there was no change in his mental condition, and he spoke as usual. On July 12th he had a fit, after which the paralysis increased. His right arm remained powerless but his leg shortly regained power. During August the patient improved, regained a certain amount of power in his right arm, and more in his leg. In the first half of September he deteriorated, his arm and leg dwindling considerably, and he was reported to have had several slight fits at night. On Sept. 15th a pustular eruption like a half oval in shape appeared over the lower part of the abdomen. He became suddenly comatose on Sept. 30th, and continued so till his death on Oct. 3rd, 1891—three months exactly after the date of his first attack. I thought his first seizure due to an apoplexy in the left hemisphere, in the region of the centres controlling the arm and leg. I considered that the slight fits which were from time to time reported as affecting him at night (though I never was fortunate enough to see him in one) were caused merely by the cerebral irritation consequent on altering blood-clot; and I thought the final attack with complete coma was due to a further and more extensive hæmorrhage, probably in the same locality as the first. In considering the patient's case the question of brain tumour was discussed; but I decidedly favoured the diagnosis of apoplexy from the suddenness of the initial seizure, the partial recoveries of power which took place in the implicated members, the absence of the train of mental phenomena usually witnessed with growing tumours, and the character of the final and fatal seizure.

A post-mortem examination was made forty-one hours after death. The body was rather emaciated. The organs

Digitized by Google

were carefully examined, their condition noted, and their weights recorded; and, with the exception of the brain, they were so far normal as not to call for comment. I shall therefore merely quote from my register the account of the appearances of the contents of the skull. Head: scalp thin, calvaria thickened; dura mater was not adherent to the bone, nor was it thickened. The state of the other membranes does not call for notice. On separating the hemispheres there was found to be a tumour the size of an orange in the right hemisphere; it was placed immediately above the lateral ventricle of that side. In consistence it was firm; it appeared encapsuled, and required no dissection to remove it from the brain. The tumour included the gyrus fornicatus and corpus callosum, or had displaced these and caused their atrophy; it lay rather more posteriorly than anteriorly. It did not cause any change in the appearance of the surface of the brain, and its presence could not be detected till the hemispheres were separated. The tumour weighed five ounces. Section of the brain showed no naked-eye changes other than atrophy of the grey matter. The arteries at the base were atheromatous. I examined a minute portion of this tumour, and found large, round, and spindle cells; but I was so much astonished at finding such a large tumour with such a short known period of illness, with such an onset and train of symptoms, that I asked my friend, Dr. Coats of Glasgow, to examine the tumour and give me a report upon it. I told him I had diagnosed sanguineous apoplexy, and that I was exceedingly surprised at the post mortem revelations. The following is the report with which Dr. Coats kindly furnished me:—

"The specimen sent is a pyriform mass, measuring, after preservation in alcohol, 2¾ in. × 2¾ in. × 1¼ in. It is very firm to the touch and generally smooth on the surface. A section having been made through the mass from apex to base, the cut surface is seen to present a somewhat varied appearance. The greater part shows a brown colour, and this presents frequently an appearance of partial disintegration, but without any absolute formation of cavity or cyst. Besides this brown substance there is a whitish structure which looks like fibrous tissue; this is especially seen at the surface, where there is an approach to a capsule formed by this fibrous-looking tissue; but it also extends at one place for some distance into the substance of the mass. Microscopic examination shows the layer on the surface to be composed essentially of spindle-shaped cells. This layer is not absolutely continuous, but covers most of the surface, and it is thin, attaining generally to about the thickness of the twenty-fifth of an inch, although sometimes extending considerably more. In connexion with this layer, but even more in the parts immediately beneath, there are frequently groups of large vessels, thin-walled and distended with blood. Beneath the spindle-celled layer the mass of the tumour is composed of a rather indefinite structure. There are many round cells, which to a considerable extent lie in masses separated by fibrous matter. This fibrous matter has, when the section is treated by ordinary methods, a vague structureless appearance. It runs among the cells forming a kind of basis, and often assuming greater proportions, so as to form strands dividing the masses. It has not, however, the aspect of wavy connective tissue, and on staining it shows no nuclei apart from those of the contained round cells. The appearance of this fibrous matter, suggested fibrine, and this view is completely confirmed by staining with Weigert's fibrine stain. This brings out frequently the finely fibrillated appearance of fibrine and shows that it extends intimately amongst the cells."

Dr. Coats is of opinion that this has been a large blood-clot, which was undergoing the process of organisation. The stages of this process are similar to those in the organisation of a thrombus, as described and illustrated in Coats' Manual of Pathology, second edition, p. 70. After the blood has coagulated there is first a penetration and replacement of it by round cells and bloodvessels, this being the stage represented in the greater part of the present specimen. After this the round cells elongate and spindle cells are produced. The process extends from without inwards, and here the surface has alone got the length of spindle-cell tissue. It is very unusual for a coagulum to undergo this process in the brain, but it is also very unusual for a patient to survive after such a large hæmorrhage as this must have been.

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

CONVULSION TREATED BY COMPRESSION OF THE CAROTID.

BY WALTER C. HEARNDEN, M.R.C.S.

IN the issue of THE LANCET of Jan. 2nd there was an annotation giving an account of Dr. Leopold Roheim's treatment of eclampsia by compression of the carotid. The following case occurred in my practice the other day, and from the rapid success of the treatment I think it worthy of record:—

A. H——, widow, aged sixty-one, had been under my care as a pauper patient on and off for some years suffering from chronic rheumatic gout. She was seized with influenza and had a severe attack of bronchitis, which made her very weak, and I had great difficulty in obtaining any nursing or assistance in feeding her. However, she was doing fairly well; when on seeing her on the 15th I found she had paralysis of the right side of the face, arm, and leg. I saw her on the following morning, and in the evening at half-past ten I was sent for to see her, as she was said to be dying. When I arrived I found her in a fit, which the attendant said had been going on for two hours. Her eyes were turned to the right, face and body twitching, and she was puffing away like a steam engine. I looked on it as a case of embolic plugging in the left hemisphere and hyperæmia of the right, as the eyes were turned to the right side; and, having Dr. Roheim's treatment fresh in my mind, I thought I would compress the right carotid. I found it rather difficult, the patient being very fat, the throat moving up and down in the convulsion, and the carotid beating with such force that it was difficult to prevent it running under the thumb. I used the thumb to compress, the rest of the hand getting power from behind the neck. In a few seconds only the twitchings began to cease, then the breathing grew slower and deeper, and in not more than a minute and a half or two minutes the face grew calm, the eyes regained their position, and there was an attempt on the patient's part to wipe the lips with the sound hand. I then left off the compression. For a minute or two the patient went on breathing calmly, then suddenly the eyes went up to the right, the face twitched, the breathing became again puffing, and the body was convulsed. I immediately compressed the carotid again as firmly as possible, and had the great satisfaction of seeing the patient in certainly less than two minutes come out of the fit, give me her hand, and pull herself up in bed, and, although dazed, still sufficiently clear to attempt to put out her tongue when told to do so. I left her to the nurse and she had no return of the fit. I know of no other treatment that could have been adopted in an emergency that would have so rapidly relieved the patient.

Leatherhead, Surrey.

"OCCLUDED OS AT FULL TIME."

BY ROBERT S. COCHRANE, M.B. DUB., F.R.C.S.I.

UNDER this heading two cases are reported by Dr. Nash in THE LANCET of Jan. 30th. About a year ago I met one very similar, which may perhaps be worth publishing.

On the evening of Feb. 25th, 1891, I was called in with my friend, Dr. Atkinson, to the following case. A primipara, thirty years of age, in labour over twelve hours. Pains very frequent and severe. On examining, we found the head low down in the pelvis, completely covered by the uterus. Neither of us could detect any trace of an os; no thickening or roughness, or the least depression appreciable by the finger. The pains increasing and becoming more violent, we drew the patient over to the side of the bed, and introduced a large-sized Ferguson's speculum. Through it, and with the aid of a strong light, we were able to see a very slight indentation where we would expect to find the os. Keeping the speculum in position, we pressed a sound

Digitized by Google

against the spot, which soon admitted it, a few drops of blood escaping. The sound was moved round between the head and the womb. By degrees with the fingers we dilated sufficiently to get in a small Barnes' bag. Dilatation rapidly proceeded, the membranes were ruptured, and a healthy child was safely delivered with the forceps.

In this case, had the head not been low down in the pelvis, thus enabling us the more readily to use the speculum and detect the position of the occluded os, there seemed no alternative but to incise the uterus at its most dependent part.

Longford, Ireland.

A CASE OF ACUTE ORCHITIS FOLLOWING INFLUENZA.

By T. GORDON KELLY, M.D. DUB., &c.

IN connexion with the case recorded by Dr. Harris in THE LANCET of Jan. 2nd the following notes may be of interest.

On Jan. 3rd I was called to see a man, J. C——, aged thirty-two. He was complaining of sickness of the stomach, pains in his head, limbs, and back, and a slight nasal catarrh. His temperature was 102·8°; pulse 120. I diagnosed the case as influenza, and put him on quinine, dilute hydrochloric acid, and bark, and a nourishing but plain diet. On Jan. 12th he had become almost quite well again, but had not left his room; and when visiting him again on the 13th I found him complaining of pain, swelling, heat and redness of his left testicle. Temperature 102·4°. I gave him a smart purgative, and had the scrotum supported by a pillow placed edgewise between his thighs, and as the pain was very great I applied belladonna over the scrotum and along the groin. He got on well, and by Feb. 1st had become convalescent.

This case seemed to me to be one exactly similar to that recorded by Dr. Harris, since in this, as in his case, the patient never left his room, had no urinary troubles, and could not account for the swelling in any way. As regards the orchitis, I can only imagine that in some way the influenza brought it on.

Desford, Leicester.

CASE OF UNUSUAL MUTILATION IN CHILDBIRTH.

By J. M. BARBOUR, M.B.

THE following case is perhaps unique in the "accidents" of midwifery.

M. K——, an unmarried woman travelling *alone* in a compartment of a suburban train, was suddenly seized with labour pains. Feeling a protrusion from the vagina, she states she attempted with some force to deliver herself, and broke the presenting limb—an arm. In a moment of pain and frenzy she took a table knife from a tiffin basket, severed the limb above the elbow, and threw it from the carriage window. A few minutes after she alighted from the train, and walked half a mile home. When seen, an hour after this incident, a considerable quantity of arterial blood had escaped from the vagina into cloths and vessels, but an excellent pulse and an entire absence of pains hardly lent credence to her story. On examination the vagina was occupied by a ragged projection, which proved to be the "balance" of an arm presentation. The patient was placed under chloroform and much difficulty was experienced in turning, the management of a jagged stump greatly hindering manipulation. Eventually a full-grown, well-nourished male child was delivered dead, with the right arm severed about two inches above the elbow. There was no funis pulsation; the stump was pale and flaccid, with a general pallor of the entire skin. The uterus was douched twice daily with solution of perchloride of mercury, and the patient made a good recovery.

This case singularly illustrates the exemption from criminality where mutilation occurs *before the child is free from the maternal passages.*

LONDON HOSPITAL.

FRACTURE DISLOCATION OF THE SECOND LUMBAR VERTEBRA; LAMINECTOMY; RECOVERY.

(Under the care of Mr. C. MANSELL MOULLIN.)

THE case is of interest from the way in which it illustrates an observation of Mr. Hutchinson that in fractures of the lumbar spine there is a possibility of recovery altogether unknown higher up in the region of the spinal cord, and also because it bears out the recommendation as regards treatment given by Thorburn for accidents of this particular locality—namely, that they should be left alone for a time to see how far spontaneous recovery will take place, and then, if this is not satisfactory, trephined before degenerative changes have advanced too far. In one point it differs materially from the majority of the cases he quotes According to his observations, the nerves which emerge from the spinal foramina low down are always, or nearly always, more severely injured than those which issue higher up, and that in spite of the fact that while they are still contained in the spinal canal, they lie nearer the axis, and might therefore be expected to enjoy a greater degree of immunity. In this case, on the contrary, the one that suffered most was the second sacral, while the fourth must have escaped almost altogether. There was, it is true, retention of urine, but as it lasted only two days it can only have been due to shock; and though there was some doubt about it at first, certainly after he had been in hospital a week the external sphincter acted well. It is to be regretted that the cutaneous sensibility of the parts supplied by the pudic and lower sacral nerves was not noted. The nature of the injury does not admit of question: the second lumbar vertebra was displaced from the third. Probably as pure dislocation in this region is almost impossible, there was a fracture in connexion with the articular processes, but no evidence of it was obtained at the operation. The cord was above the level of the injury and escaped. So far as the nervous system was concerned, the whole of the violence fell upon the cauda equina; the nerves in the intervertebral foramina do not seem to have suffered. The conditions resulting from injury to the spine, for which Mr. Thorburn recommends operation, in addition to the injuries of the cauda equina, are meningeal hæmorrhage and impacted fracture of the lamina only. Much interesting information on this question may be found in his Jacksonian prize essay, as also in the papers by Gurlt,[1] Ashhurst,[2] and Werner.[3]

D. B——, thirty-eight years of age, a labourer, of average height and strength, was sent to the London Hospital on Jan. 7th, 1891, by Dr. H. C. Male of Grays, Essex, who also kindly forwarded the early notes of the patient. On Jan. 1st, while working in a chalk pit, a ledge upon which he was standing gave way, and he fell, with a considerable amount of débris, some five-and-twenty feet. He does not appear to have been buried or crushed in any way. For a few minutes he was unconscious; then he recovered sufficiently to sit up with assistance, but he did not make any attempt to stand—he felt he could not. His legs were completely paralysed, so far as motion was concerned; there was severe pain in his back, and what he described as pins and needles running down from his loins to his feet. A few hours later, after he had been carried home, he so far improved that he was able to move his right leg a little. Both legs felt numbed; sensation was only slightly impaired upon the right side, but was almost lost upon the left.

Dr. Male, who saw him about an hour after the accident, finding there was considerable displacement, determined to

[2] Injuries of the Spine.
[3] Die Trepanation der Wirbelsaule.

Digitized by Google

try the effect of manual extension, and succeeded in reducing the deformity, though he could not altogether remove it. Unfortunately, a day or two later, in carrying the patient down some narrow stairs preparatory to conveying him to hospital, a great deal of the advantage that had been gained was lost, and the patient's strength was too much exhausted to permit a second attempt being made. For the first two days there was retention of urine, then the bladder began to recover; but for a time micturition was very slow, and the stream was ejected without force. The bowels were relieved by enemata. On the seventh day after the accident he was brought to the hospital by the ambulance without any difficulty.

On admission the second lumbar vertebra was found to be displaced forwards upon the third, and rotated slightly towards the left, so that the right transverse process was more deeply sunken. Extension was tried, but it had no effect upon the deformity. The patient could flex the right hip and raise the knee with the foot resting on the bed. The quadriceps and all the muscles below were paralysed. On the left side the loss of power was more extensive; the patient was unable even to move the hip-joint. Tactile sensation was good all over the right side (the skin over the gluteal region was not tried), and on the left above the knee; below it was considerably impaired, especially over the foot. The lower extremities felt dead and numbed, and at times there was a pricking sensation in the feet and thighs. Micturition was carried out very slowly. The bowels were constipated; and though the evidence was not satisfactory, it seemed on the whole that there was some loss of power over the external sphincter.

For about three weeks the condition of the patient steadily improved. On the right side the quadriceps recovered, so that the knee could be straightened and the whole limb raised up from the bed, and some power returned in the gastrocnemius. On the left the hip could just be flexed, drawing the foot up. Sensation became practically normal, except over the outer side of the left leg and the left foot. The knee-jerks, however, remained absent; there was no patellar reflex. The nerves continued to be very tender on pressure, and the muscles below the knees on both sides wasted until there was scarcely any fleshy substance left. All the muscles reacted to galvanism, and all but the left tibialis anticus to faradaism. At this point matters became stationary, and as after some weeks there was no evidence of further improvement, the patient was advised to undergo an operation.

Laminectomy was performed on March 3rd (nine weeks after the accident). An incision five inches long was made in the middle line of the back, and the periosteum and muscles stripped off the spines of the second and third lumbar vertebræ. The spines were then removed with bone forceps, the laminæ divided with a trephine, and the dura mater exposed. As this bulged up at once into the gap, and appeared to be under considerable pressure, the right lower articular process of the second lumbar vertebra, which was twisted round upon the third, was removed as well. This seemed to give sufficient room. No vessels required tying. The wound, which was very deep, was sponged out with corrosive sublimate, dusted with iodoform and fastened with deep sutures, and sponges wrung out of carbolic were placed on either side to secure sufficient pressure. The shock after the operation was very slight; there was no retention of urine, and the temperature rose only to 101° on one occasion. A small portion of skin that had been bruised by a retractor sloughed at the upper end of the wound, and there was a little suppuration around one of the deep sutures. Otherwise it healed well and without any trouble.

The day after the operation the patient complained of severe shooting pain in the left ankle, but stated that the sensation of numbness had greatly diminished. The next day the extensors of the toes upon the right side, and the peronei upon both, were able to contract a little. On the sixth day the left gastrocnemius began to recover, and, although there was a good deal of shooting pain and tenderness down both legs (especially the left) for some weeks longer, from the time of the operation the patient gradually regained power over all the muscles except the tibialis anticus and the extensors of the toes upon the left side. Galvanism and massage were commenced upon March 26th, and the patient was allowed to sit up on April 15th. By the beginning of June he had left off crutches and could walk fairly well; the only inconvenience was the loss of power over the dorsal flexors of his left ankle and the consequent dropping of the toes. Several attempts were made to relieve this by means of rubber accumulators, but they seemed to give him more trouble than the complaint.

The patient was shown at the Clinical Society on Jan. 22nd, 1892. He could walk up- and down-stairs without a stick, and stoop down and lift himself up without the least difficulty. The toes of the left foot still dropped, but the muscles were apparently regaining power.

Remarks by Mr. MANSELL MOULLIN. — The shock of the accident may be considered responsible for the loss of consciousness, the general paralysis and loss of sensibility over the lower part of the body, and the retention of urine. These symptoms at least passed off very much sooner than they would have done had they been due to hæmorrhage or pressure. Of the rest, those which disappeared spontaneously in the course of the first three weeks may be attributed to simple bruising, extravasation of blood, or the displacement of the bones, and there can be no doubt that the early reposition of the fragments by Dr. Male, although it was only partial and relapsed to some extent, was of material benefit. The rapidity with which those that had not already disappeared began to clear up after the operation may be regarded as proof that they were really due to compression. It is probable from the early loss of faradaic excitability that the nerves supplying the extensors of the toes and the tibialis anticus on the left side were hopelessly crushed; but I have regretted since that I did not open up the canal more freely upon the left side, as they might then have had a better chance of recovery.

BRADFORD INFIRMARY, YORKS.

COMPOUND DEPRESSED FRACTURE OF THE SKULL; APHASIA; FACIAL AND BRACHIAL PARESIS; TREPHINING; RECOVERY.

(Under the care of Mr. APPLEYARD.)

THIS case of compound fracture of the skull with depression of the bone is an example of the rarer group of injuries of the cranial vault, in which localised symptoms dependent on the cerebral injury attract most attention and call most urgently for relief. It also illustrates the satisfactory recovery which results nowadays from application of the trephine with elevation of the bone fragments in these injuries, when it is possible to render the wound quite aseptic. In such there is no doubt of the necessity for operation. For the notes of this case we are indebted to Dr. J. Lacy Firth, house surgeon.

S. H——, coalminer, aged forty-three, was working in the shaft of a mine at 10 A.M. on July 16th, 1891, when a sharp-angled stone weighing about 7 lb. fell upon his head from a height of seven or eight feet. For a minute or two he lost consciousness, but then recovered, and with support was able to walk home, a distance of half a mile. At 3 P.M., five hours after the injury, the patient was brought to the Bradford Infirmary in a cab. He was still able to walk with support.

On admission the patient was pale and looked ill; lips blue; he was with difficulty able to sit up. On the left side of the scalp, vertically above the external auditory meatus and two inches from the line of the sagittal suture, was a triradiate and contused wound. On raising the anterior flap the parietal bone was found to have sustained a depressed fracture. The depression was roughly the shape and size of a broad almond with the long axis transverse. The depressed fragments were absolutely immovable. The depth of the depression was about one-third of an inch. A good deal of mud had entered the wound. The patient was quite conscious. When asked his name he strove apparently to recollect and utter it, but had to make several efforts before succeeding, and immediately afterwards said "That's it," and was obviously pleased with his success. The expression "That's it" he uttered several times when trying to say other words. Impaired articulation and hesitation in the formation of words rendered his speech very difficult to understand. He appeared to perfectly understand all that was said to him. The tongue on protrusion deviated to the right of the middle line. There was depression of the right corner of

Digitized by Google

the mouth when at rest, and impaired power of raising it when asked to raise the upper lip. He could not raise the right arm from the bed, and had no power of grasp. There appeared to be no loss of strength in the right leg. Tactile sensation tested roughly appeared to be unimpaired.

Trephining by Mr. APPLEYARD.—At 7 P.M., nine hours after the injury, chloroform was given. The head was shaved and cleansed with soap, turpentine, and a 1 in 1000 perchloride of mercury solution in turn. The wound was enlarged and the quarter-inch trephine twice applied—one complete ring and two-thirds of a second ring of bone being removed. In both cases the fragments of the outer table came away in the trephine first, and the internal table was sawn through separately. The depressed fragments were now easily removed—first the outer table fragments, and next the inner. The two tables had been separated by the injury of the diploë. The inner table was more extensively fractured than the outer, and loose fragments of the inner table were removed from beneath the uninjured outer table. The dura mater appeared uninjured. No sutures were applied. The wound was dressed with cyanide gauze and sal alembroth wool. Four hours after the operation the patient could raise his arm from the bed.

Second day.—There was no noticeable affection of speech, and the patient had slight grasping power.

Third day.—Wound dressed; it looked well.

Fourth day.—Wound dressed. The anterior flap pulsated markedly. No tenderness or swelling. Grasp remains weak, and the facial and lingual paresis is unaltered.

Fifth day.—Wound healing rapidly. The hand and arm are weaker than yesterday.

Sixth day.—Power of grasp lost again. The triceps appears to be completely paralysed, but the biceps is fairly powerful. For the last twelve hours the patient has had sensations of pins and needles in the forearm from the wrist to elbow.

Eighth day.—Sensation altered, as on sixth day. Grasp still almost absent; facial, lingual, and upper arm paresis less marked. A drop or two of clear serous fluid was expressed from beneath the anterior flap. Morning temperature: right side, 97·6°; left, 96·8°.

Ninth day.—Power of grasp considerably increased. There is incoördination of movement. On attempting to pick up or reach an object the hand digresses from side to side two or three times before succeeding. A drop of serum was expressed from beneath the anterior flap.

Fifteenth day.—The incoördination is less marked and also the disturbed sensation.

Twenty-third day.—There is fair grasping power in the right hand. Facial and lingual palsy very slight. Slight incoördination as before.

Thirty-first day.—Patient discharged.

The patient was seen three months after the accident and said then that he felt perfectly well with the exception that the little finger was somewhat numb and useless. He could, however, flex and extend the thumb perfectly and tactile sensation was perfect. A fortnight later he was seen again. He feels as well as he ever felt in his life. The little finger has lost its numbness. Scar firm. No tenderness of scalp No headache. He has been doing his ordinary work a fortnight.

To the above notes it should be added that the highest temperatures recorded (axillary) were on the evenings of the first three days, and were respectively 100·8°, 99·6°, and 98·6°. After the third day they were for the most part slightly subnormal, and only twice reached the height of 98·6°. For the first fourteen days the temperature in the right axilla was slightly higher than in the left. The difference varied from 1° to 2° F. On three occasions only was it equal on the two sides.

Remarks.—Noteworthy features in the above case appear to be the slight and transient concussion, the difference in extent of the injury to the external and internal tables of the calvaria, the healthy appearance of the dura mater, and the presence of the symptoms of numbness and incoördination in the forearm and hand, the former being first observed on the sixth day and the latter on the ninth, and both persisting to the end of convalescence, and disappearing *pari passu* with the motor paresis. Do not the latter symptoms point to segmental sensory representation in the cortex? and do they not fall more in accord with Dr. Bastian's view of the kinæsthetic function of the cortex in the Rolandic area than with Dr. Ferrier's view of the purely motor function of that area

Medical Societies.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Gelatiniform Degeneration of Hydatid Cysts.—Changes in the Blood in the Course of Rheumatic Attacks.

AN ordinary meeting of this Society was held on Feb. 9th, the president, Mr. Timothy Holmes, in the chair.

Dr. MITCHELL BRUCE and Mr. MARMADUKE SHEILD communicated a paper on Gelatiniform Degeneration of Hydatid Cysts. The authors first related the case of a patient, a male aged forty, who was the subject of a large hydatid cyst. The symptoms commenced very obscurely, and the diagnosis was at first dubious. When the usual signs of hydatid cyst declared themselves aspiration was performed, but no fluid escaped, and the cannula was found blocked with tough, jelly-like material. The characteristic hooklets were discovered in this under the microscope, and the diagnosis was verified beyond a doubt. As the cyst was rapidly increasing direct hepatotomy was performed. Much difficulty arose in the operation, from the depth at which the cyst was located in the liver. The operation was described, and the method by which the cyst was evacuated and secured to the abdominal wound. Good union took place, no peritonitis occurred, and the cavity contracted. Unfortunately the patient died eight days after the operation, with all the ordinary symptoms of delirium tremens. His previous habits, for upwards of twenty years, strongly predisposed him to this complication, and it is believed that otherwise the operation would have been quite successful. The authors discussed the general question of solidification of hydatid cysts. They next referred to the peculiar degeneration exemplified in the case related. Its rarity was pointed out and its clinical importance insisted upon. Finally, the surgical question was raised as to the best method of dividing a considerable thickness of liver tissue, with special reference to the causation and checking of hæmorrhage.

Dr. ARCHIBALD E. GARROD contributed a paper on the Changes in the Blood in the Course of Rheumatic Attacks. The work of Malassez, Baxter and Wilcox, Hayem, and Maragliano and Castellino upon the changes in the blood during rheumatic attacks was referred to, and the results obtained by the three last-mentioned observers were quoted at some length. The author's conclusions were based upon some eighty examinations of the blood of rheumatic patients, as many as six or eight observations having been made in the course of the attack in some cases. The corpuscles were counted with a Thoma Zeiss hæmocytometer, 256 squares (equal to 32 squares of Gowers' hæmocytometer) being counted on each occasion. For the estimation of the hæmoglobin percentage a von Fleischl's hæmometer was employed. Results of comparisons of these instruments with others of Gowers' pattern were given. Observations on ten healthy persons and ten chlorotic patients with the instruments used are quoted as standards for comparison. The following conclusions were arrived at:—An attack of rheumatism is always attended with a considerable diminution of the number of red corpuscles, which diminution commences very early in the attack. When convalescence sets in the lost corpuscles are rapidly replaced. In acute cases the loss of red corpuscles is usually about 1,000,000 per cubic millimetre. The rapidity of the diminution and repair is such that within as short a period as ten or eleven days a million corpuscles may be lost and replaced. The development of a fresh rheumatic manifestation during convalescence is attended by a fresh fall, and in this way the phenomena of loss and repair may be repeated several times in the course of the attack. In prolonged attacks there is not a progressive diminution of the number of red corpuscles, but, on the contrary, the numbers remain at or about an even low level. There is no real connexion between the variation of the red corpuscles and the temperature curve, the blood changes being equally marked in afebrile cases. Indeed, these variations afford a far more delicate index than does the temperature chart of the activity of the rheumatic process. The changes in the blood may be equally conspicuous whatever the nature of the rheumatic manifestation which they accompany, whether arthritis, pericarditis, erythema, or pleurisy. The changes

Digitized by Google

are not due to salicylic treatment, being equally well marked when no salicylate is given. A loss of corpuscles is sometimes observed when the patient first leaves his bed, but this is not a constant phenomenon, being sometimes absent and sometimes replaced by a fall of hæmoglobin. The variations of the percentage of hæmoglobin frequently follow those of the corpuscles, the worth of the individual corpuscle (obtained by dividing the percentage of hæmoglobin by the percentage of corpuscles) remaining constant. A tendency to falling worth is manifested in many cases, and not only at the period when many new and incompletely developed corpuscles are present. When the worth falls during the acute attack the diminution is usually only transitory; but a progressive fall of worth may set in during convalescence, producing a condition of more or less chronic anæmia. Nevertheless, any conspicuous diminution of worth between the first and last observations is somewhat exceptional. In some few cases the hæmoglobin percentage rises rapidly for a time; whilst the percentage of red corpuscles remains constant, or is falling. Examples of this are quoted which rest upon double observations. As Dr. MacMunn has pointed out, uro hæmatoporphyrin, a pigment discovered by him, is usually present in the urine in considerable quantity during rheumatic attacks; and, since this pigment is one of the products of the action of reducing agents upon hæmatin, it seemed probable that some connexion might be traced between its appearance in the urine and the changes in the blood. In eight cases the blood and urine were simultaneously studied with a view to ascertaining whether any such relation exists, and it was found that the appearance of uro-hæmatoporphyrin in the urine and its disappearance therefrom did not bear any recognisable relation to the variations in the number and worth of the red corpuscles. Patients who were passing uro-hæmatoporphyrin in the urine throughout their stay left the hospital with no deterioration of the blood. Hence it is concluded that the appearance of this pigment in the urine, assuming it to be derived directly from blood-pigment, does not indicate any excessive destruction of hæmoglobin, but rather a perversion of the ordinary processes for the elimination of the effete blood-pigment. The anæmia of rheumatism is of two kinds—an acute oligocythæmia which is rapidly recovered from, and a more chronic condition of pseudo-chlorosis, which may outlast the attack, and which is only observed in a small proportion of cases. The former variety calls for no special treatment, but iron is often of great value in combating the second and more lasting form of anæmia. The consideration of the variations in the number of white corpuscles, and of certain other phenomena, is reserved for a further communication.—Dr. WILCOX said his investigations showed that the blood was reduced in rheumatism, both as regards its corpuscles and the amount of fluid, very much as in other forms of anæmia. During recovery the corpuscles increased in number very rapidly by the addition of new-formed elements; the colour was also greatly and quickly improved by the administration of iron. He did not therefore attach too great importance in slight variations during convalescence. The amount of fluid in circulation was largely accountable for the apparent number of corpuscles as estimated by the hæmacytometer, though their actual quantity might not be affected.—Dr. STURGES referred to the constant association of anæmia with acute rheumatism, particularly in children. It being sometimes very difficult to recognise the disease in young subjects owing to the absence of the usual signs, such as pain &c., the value of acute anæmia as an indication of rheumatism in such cases was illustrated by two children recently under his care, who whilst in this condition developed a pericardial rub and an endocardial murmur.—Dr. OGIER WARD, in connexion with this point, mentioned a very similar instance, and referred to another feature—viz., the loaded condition of the urine, which had a specific gravity of 1030 or upwards. He quoted a case in which the pallor, a faint endocardial murmur, and great concentration of the urine all disappeared under treatment for rheumatism.—Dr. ALFRED GARROD, in reply to Dr. Wilcox, said it was the constancy with which anæmia accompanied rheumatism in children that led him to undertake the present investigation. He laid most stress on variations in "worth" of the corpuscles, this not being affected by variations in the quantity of fluid in circulation. He distinguished also between the early acute oligocythæmia and the later tendency to a progressive fall in the "worth" of the corpuscles which occurred during convalescence in some cases.

Dr. KESER read a paper on the Treatment of some forms of Chronic Bronchitis by the water of Weissenburg (Switzerland). He related two cases of chronic bronchitis in which the plan of treatment followed at Weissenburg has been used with success. The first patient was a lady, forty-eight years of age, who had suffered from bronchitis and emphysema for ten years. There was a considerable amelioration in her condition during the summer months, but never a complete disappearance of the symptoms. She had tried the seaside and country air in England and on the Continent, but without permanent benefit. Treatment by drugs had a temporary effect only. She went to Weissenburg in 1890 and 1891, with the result that the bronchial affection has now entirely disappeared; there is still some emphysema. The second case is one of chronic bronchitis in a phthisical patient, aged forty-three, who was first seen eight years ago. In 1890 the condition of the lungs was satisfactory, but the bronchial affection had increased to an alarming extent. The patient spent several weeks at Weissenburg in 1890 and 1891, and on his return last year nothing abnormal could be found in the chest except prolonged expiration at the right apex. There are at present no signs of bronchitis. Weissenburg is situated in the neighbourhood of Thun, at a height of 874 metres, in the midst of extensive pine woods. Few places are so completely free from wind and dust. The water contains in one litre 0·95 of sulphate of lime, 0·3 of sulphate of magnesia, and many other substances in smaller quantities. The temperature of the water is about 23° C. The patients are expected to observe strict rules concerning diet, amount of exercise, &c. —The PRESIDENT made some inquiries relative to the procurability of the water.—Dr. SYMES THOMPSON mentioned Malvern as affording nearly parallel advantages. He said the water there was very pure, and that as much as thirty tumblerfuls used to be taken before breakfast with great benefit to certain cachectic conditions associated with bronchitic trouble where the secretions were scanty and the balance between ingestion and excretion disturbed as a result of town life. Such conditions as those mentioned by Dr. Keser hastened the restoration of this balance, and it was important to know of a place where they could be found within easy access.

MEDICAL SOCIETY OF LONDON.

Splenic Anæmia in Young Children.

AN ordinary meeting of this Society was held on Feb. 8th, the President, Dr. Douglas Powell, in the chair.

Dr. WALTER CARR read a paper on Splenic Anæmia, based upon thirty cases of the disease observed at the Victoria Hospital for Children, Chelsea. Sixteen were boys and fourteen girls; in age, when first seen, they varied from two months to two years and a half. They were usually wasted, and nearly always more or less anæmic in appearance, often showing the characteristic splenic tint. The spleen was always enlarged, and in about half the cases reached the level of the anterior superior iliac spine. There was frequently also some apparent enlargement of the liver and some swelling of the external lymphatic glands. In the more severe cases hæmorrhages occurred and irregular attacks of pyrexia, both probably due simply to the profound anæmia. Examination of the blood showed the red corpuscles to vary in number from 32 to 78 per cent. of the normal, and the hæmoglobin value of the individual corpuscles to be more or less deficient. The white corpuscles were only slightly in excess, averaging about 1 to 100 red; in only one case was the proportion higher than 1 to 70. Ten of the thirty cases were known to have died either from increasing anæmia and exhaustion or from intercurrent diseases, six could not be traced, 13 had either completely recovered or were steadily improving—one alone, after two years, remained practically *in statu quo*. A necropsy was obtained in seven of the cases. The spleen was found adherent in two, in one it only weighed one ounce, in the others from four ounces to eight ounces and a half; in all it was firm, dark, and distinctly increased in consistence, but otherwise presented no very abnormal appearance, and the microscope showed the enlargement to be due to simple hypertrophy, with some increase of fibrous tissue. The liver was not found distinctly enlarged, and in only two cases markedly tougher than usual. There was no noteworthy change in

Digitized by Google

any other organ. The connexion of the disease with ague, congenital syphilis, and rickets respectively was then discussed. The possibility of a malarial origin, either direct or inherited, was referred to, and in two of the children the father had suffered from definite ague; but in the case of a boy aged two years and a half, born in India, with large liver and spleen and marked anæmia, the result of many attacks of ague, after five weeks of treatment with quinine the liver and spleen could no longer be felt, and the anæmia had greatly improved, whereas ordinary cases of splenic anæmia showed no such improvement under quinine. In fourteen of the cases there was either undoubted or probable evidence of congenital syphilis, and seven of these died, but in a large number of other cases there was no indication whatever of specific taint, and even in the most obviously syphilitic cases the spleen and the anæmia were not affected by mercurial treatment, so that the conclusion adopted was that syphilis could be regarded as a predisposing condition only, and not as the sole cause of the disease. In twenty-seven of the cases there was rickets, more or less severe, but it was argued that this could not be the real cause of the disease, because (1) in the great majority of rickety children no splenic enlargement could be discovered; (2) there was no connexion between the severity of the rickets and the size of the spleen or the degree of anæmia; (3) in certain cases there was no evidence whatever of rickets. It was argued, therefore, that splenic anæmia must be due to a separate cachexia, to which both rickets and syphilis predisposed, but which required some further definite exciting cause at present unknown for its development, and that this theory of its origin would account for the similarity in clinical course and in pathological appearances observed in all the cases, whether rachitic or syphilitic, and also for the absence of improvement under the treatment usually beneficial for the two latter conditions. The question was also discussed whether splenic anæmia occurred after infancy, and an apparent case of the disease arising and proving fatal in a boy aged seven years was described. In regard to treatment, mercury, arsenic, and quinine appeared entirely useless, but improvement seemed sometimes to result from iron given in large and increasing doses.

The PRESIDENT inquired if any alteration had been noted in the urine with regard to the quantity of uric acid. He thought it would be interesting to know more about the association of marked anæmia with enlarged spleen, as to whether they were mutually dependent on one another, and also whether there were any abnormalities in connexion with the red corpuscles such as occurred in pernicious anæmia.

Dr. LESLIE OGILVIE said that in childhood it was usual for the spleen to be relatively enlarged, and that an excess of hæmoglobin and of corpuscles was not infrequently met with. In some cases the hæmoglobin was diminished, and in some the red corpuscles appeared nucleated. There were instances of rickets showing marked anæmia, but in which the spleen was not notably enlarged. The red corpuscles in such might be actually increased in number. His experience was that the excretion of urea was increased; this was especially marked and associated with diminution of the red corpuscles during recovery. He did not think that syphilis alone produced so much enlargement of the spleen as when conjoined with rickets.

Dr. COLCOTT FOX, alluding to the enlargement of the spleen in children, said that in three years he had collected sixty-eight cases, five of which he excluded as being tubercular. In age the cases ranged from four months to two years and a half—that is, while the bone changes of rickets were progressing. He thought that when one child was affected in this way, succeeding ones in the family followed the example. He found anæmia usually well marked, the patients exhibiting a waxy, greenish tint, with flabby tissues, and commonly enlarged liver and lymphatic glands. In six cases in which the blood had been examined there was noted a diminution in corpuscles, although leucocytes appeared to be actually increased. In the majority of cases the prognosis was favourable, but in a small number the enlargement of the spleen was progressive, and quite uncontrolled by drugs. Histologically, this appeared to be due to simple hypertrophy, with some increase of fibrous tissue. The changes in hereditary syphilis were apparently identical. He considered the cause was rickets. Recovery took place under treatment with iron and cod-liver oil.

Dr. COLCOTT FOX in another series had collected all the cases of hereditary syphilis which came under his notice, fifty-five in number, of which 47 per cent. had enlarged spleen. He thought that a very large percentage of cases of hereditary syphilis ended in rickets, and that in cases of rickets with enlarged spleen it was often most difficult to exclude syphilis. He had found the spleen extending to the umbilicus in infants of a few weeks. His conclusion was that syphilis was the principal factor, aided by rickets, which might be an outcome of syphilis, and due to disturbed nutrition.

Dr. CARR, in reply, said that he had estimated the corpuscles only in the most marked cases, and that a consideration of the whole number would very much diminish the average computation. The association of the condition with rickets was not so very clear; this disease was absent in some and syphilis in others, so that a third factor appeared necessary to explain it. Apart from intercurrent disease the prognosis appeared good. Systematic observations on the urine were practically impossible to carry out in children, but so far as he had been able to note there was nothing special to remark upon. He thought the anæmia and the splenic enlargement progressed *pari passu*.

OBSTETRICAL SOCIETY OF LONDON.

AT the meeting on Feb. 3rd (Dr. Watt Black, President, in the chair) the following specimens were shown:—

Mr. ALBAN DORAN, for Dr. George Beale: Ruptured Ovarian Cyst from a child six weeks old.

Mr. BUTLER SMYTHE: Distended Fallopian Tubes.

Dr. HERBERT SPENCER: Section through Fœtus, showing Retroflexion of the Uterus caused by Distended Bowels.

Dr. JOHN PHILLIPS: Putrid Extra-uterine Fœtation, with points of Ossification, proving seven months' gestation.

Dr. PLAYFAIR: Tubal Fœtation; Hæmato-salpinx.

The election of officers was proceeded with, Dr. John Phillips and Mr. Targett acting as scrutineers. The Fellows nominated were duly elected.

The following gentlemen were elected honorary Fellows of the Society:—Sir Joseph Lister, Bart., Sir William Turner (Edinburgh), Professor Carl S. F. Credé (Leipzig), and Professor William T. Lusk (New York).

Protracted Gestation.—Dr. PAGET BLAKE narrated a case of Protracted Gestation. The patient, aged twenty-five, had been married two years, and had had two miscarriages at the third month. She menstruated on Sept. 22nd; coitus on Oct. 15th. There was no period in October. Morning sickness soon came on. Confinement was calculated to take place about July 22nd, and on this date there was an abundant secretion of milk. She continued to increase in size, and on Aug. 3rd labour apparently began, but after lasting three or four days the pains ceased, and she was not delivered until Sept. 5th, or 323 days after conception.—Dr. CHAMPNEYS thought that the evidence of protracted gestation was insufficient. There was no mention of the weight, length, or condition of nails and skin of the child, nor was the date of the return of the husband given.—Dr. ROUTH asked if the patient had a pendulous abdomen, as he believed this condition would cause protracted gestation, the uterus being unable to act properly.—Dr. CULLINGWORTH said from a medico legal point of view it would be desirable to obtain the additional information mentioned by Dr. Champneys.—Dr. LEITH NAPIER spoke to the same effect, and also said that secretion of milk and pains resembling labour pains might be found in the non-pregnant state. Most cases of so-called protracted gestation were pregnancies of ordinary duration, preceded by amenorrhœa due to other causes.—Drs. BRAXTON HICKS and PLAYFAIR offered remarks.—Dr. LEWERS mentioned the case of a patient aged forty-nine, who, after thirteen months' amenorrhœa, was found to be merely five months pregnant.—Dr. HERMAN said the history of the time of the coitus was too indefinite.

Annual Address.—The PRESIDENT then delivered the annual address, of which the following is a short abstract: "Gentlemen, in common with the whole of Her Majesty's subjects, the Council of the Obstetrical Society of London has noted with the greatest sorrow the lamented death of his Royal Highness the Duke of Clarence and Avondale. The Council have approved the proposal to petition Government to appoint a Select Committee to inquire into the question of the legal registration of midwives. The ordinary Fellows parted from us by death during 1891 number five.

Charles Verrall Willett settled in practice in Brighton in 1866, at Shoreham in 1867, and again in Brighton in 1869, at Brandon, Suffolk, in 1878, at Bristol in 1884, in West Kensington, London, in 1887, and again in Shoreham in 1891. He died on March 6th, 1891. Francis Joseph Salter of Leeds died on March 25th, 1891. William E. Steavenson, M.D. Cantab., died on June 1st, 1891. In 1882 he was appointed to organise and superintend the electrical department at St. Bartholomew's Hospital. He was a frequent contributor to medical literature. Dr. James Henry Bennet was born in 1816. He studied at Guy's Hospital, but soon left to become apprentice to his uncle, Mr. Osmond Taberer, in Derbyshire. He studied in Paris, afterwards practised in London, and subsequently in Mentone. He published several works. He became a Fellow of the Society in 1873. Edward Overman Day died August 4th, 1891, at the age of thirty-nine. He studied at Guy's Hospital, and was assistant surgeon and administrator of anæsthetics to the Royal Hospital for Children and Women, Waterloo-bridge-road. Four of our ten foreign honorary Fellows have died during the year: Professor Benjamin Fordyce Barker of New York, Professor Carl Braun von Fernwald of Vienna, Professor Scanzoni von Lichtenfels of Würzburg, and Professor Theodor Hugenberger of Moscow. [A long and interesting account of the work of each of these honorary Fellows was given.] The annual volume recording the scientific work of the Society will presently be in your hands, to speak for itself. Dr. Herbert Spencer's admirable and beautifully illustrated paper on Visceral Hæmorrhages in Stillborn Children is alone sufficient to justify the opinion that the present volume will be found to possess exceptional scientific value. In conclusion, I have to thank the honorary secretaries, and especially Mr. Alban Doran, the senior secretary, for the great assistance which they have rendered me in the discharge of my duties as President."

The usual votes of thanks to the President and the retiring Vice-Presidents and the other retiring members of council were passed. A vote of thanks was proposed to the retiring honorary secretary, Mr. Alban Doran, special mention being made of the extra work he had been called upon to do owing to the illness of the librarian, Mr. Savage.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, FEB. 5TH (CLINICAL EVENING).

Dr. PRIOR PURVIS, Treasurer, in the chair.

Ainhum.—Mr. JOHNSON SMITH, F.R.C.S., showed a case of Ainhum. The patient was a tall, muscular negro, aged thirty-eight, from Jamaica, who had been a sailor for eighteen years. Ten months ago he first complained of pain in the little toe of the right foot, and he noticed a slight constriction on the under surface; this has increased very much in depth, and extended to the upper surface. There is now a very deep constriction on the plantar and inner surfaces of the toe, corresponding to the middle of the first phalanx, and this groove is continuous with a shallow one on the dorsum. The distal portion of the toe is swollen. None of the other toes in either foot are similarly affected. There is much pain in the affected toe, which prevents the patient from sleeping at night.

Dr. EZARD showed a child seventeen months old, with a Sessile Papilloma on the under surface of the tongue, in the middle line, of the size of a threepenny-piece.

Dr. DOCKRELL showed cases of Lupus, Erythematous Leucoderma, Alopecia Areata, and a case of Mixed (diffuse and circumscribed) Scleroderma.

Mr. PURVIS, B.Sc., showed a specimen, of Multiple Abscess of Lung from a child aged three years, following measles and otitis media; and a specimen of Hypertrophied Heart (weight 16 oz.), with pericarditis and mitral disease.

Dr. FULLERTON showed specimens, with microscopical sections, of Carcinoma (cylindrical celled), of Pleura, Peritoneum, and Ovaries from a patient who died five months after the first symptoms appeared.

CLONMEL WATERWORKS.—The Clonmel Corporation have arranged to have constructed waterworks for the town at an estimated cost of £14,437.

Notices of Books.

Medical Notes and Essays. II. Influenza. By Sir PETER EADE, M.D. Lond., F.R.C.P. London and Norwich: Jarrold and Sons. 1891.—A few years ago the writer of these Notes and Essays published his experiences on diphtheria in a little volume, which gave a clear insight into the prevalence and propagation of that disease in country districts. He now has issued this "second fasciculus" of his Notes and Essays to enlighten us as to influenza in East Anglia, and the papers he has collected are well worthy perusal. It is valuable to have the opinion of so observant a practitioner as to the contagiousness of the affection, and, whilst admitting this to be proved, he yet thinks that it is also propagated by aerial infection. Nevertheless, he says that the intense contagiousness which the extremely rapid spread of epidemics implies is not borne out by the history of the disease in various public institutions; "whilst the fact that stands out most prominently in the records is the comparatively small proportion of the inmates attacked, and that even those brought into close contact with each other, or sleeping in contiguous beds, by no means *necessarily* became infected by their sick neighbours" (p. 10). The author's recollections carry him back to the great epidemic of 1847–48—a fact that lends great interest to his observations of the outbreak of 1890–91, with which he here chiefly deals. In succinct manner he describes the leading features of the attacks, and of much value are his observations on the more or less remote sequelæ (p. 17), in which nervous affections play a large part. He does not think that influenza *per se* has been so fatal during this epidemic as on previous occasions, but draws attention to the severity and fatality of the pulmonary complications. His remarks on treatment are judicious and pointed. He reproduces a note published in these columns (March 16th, 1878) on a limited epidemic of influenza in East Anglia in 1878, as well as his paper (THE LANCET, Feb. 1st, 1890) on "Influenza in East Anglia in 1890," and one on "Influenza in 1891" read at the Bournemouth meeting of the British Medical Association. Of considerable value are the records he furnishes of influenza in public institutions and the notes of cases observed in his practice.

New Fragments. By JOHN TYNDALL, F.R.S. London: Longmans, Green, and Co. 1892.—Professor Tyndall possesses in an eminent degree the faculty of writing readable books, and this latest product of his pen will sustain the reputation in this respect that he has long enjoyed. As an interpreter of scientific doctrine to a popular audience there is probably no writer of the English language at the present day who can surpass him; and it is no small part of his merit that the topics which he selects for discussion are such as "come home" to every-day men and women. Hence the distinguished position which he holds in popular esteem—a position which would alone create in his behalf a title to recognition by all who desire the spread of scientific knowledge and the diffusion of scientific sympathies and modes of thought. But Professor Tyndall has still higher claims to recognition, in the fact that he turns this position to excellent account, and is not less judicious in selecting his material wisely than successful in exhibiting it in a fascinating manner. This happy combination of qualities is well illustrated by two papers in the present collection of articles—those, namely, on Louis Pasteur, and on the Origin, Propagation, and Prevention of Phthisis. These both treat of subjects that have been much discussed of late, and the reverberations of controversies not yet extinct may be discovered easily enough in Professor Tyndall's discourse. It is not, however, as a controversialist that he

Digitized by Google

comes before his readers, but rather as the reaper of ripe doctrine, who places the results of his labour at his readers' disposal, and leaves for subsequent harvesting the points which have yet to be matured by further discussion. The lurking dangers of such an operation are, on the one hand, that the writer may mistake his own views for the approved doctrine, and, on the other, that he may induce his readers to substitute a little knowledge for a wise reliance upon the opinion of those who know better. But these papers will not incur any such reproach. The paper on Pasteur is, indeed, largely biographical, and the references to the spontaneous generation theory are not likely to provoke contradiction. But the formal subject of the paper upon phthisis presents many perils. The paper, however, hardly corresponds to its title. The origin and prevention of phthisis are not effectively discussed, unless, indeed, by prevention is to be understood the avoidance of such methods of disposing of the sputum as confessedly conduce to the dissemination of its desiccated residue in the form of dust through the atmosphere. To enforce this lesson is, indeed, the motive and burden of the essay, and very effectively it is enforced. Such a lesson can hardly be misunderstood, and the author of the paper may be congratulated on having made an important contribution to the formation of a sound public opinion upon this eminently vital subject. The remaining papers are very diverse, not only in respect of the subjects treated, but also in respect of the classes of readers to which they will appeal. In some, as noticeably in the paper on Life in the Alps, there are marks of haste and some carelessness, but upon the whole this volume is fitted to add to the reputation even of its distinguished author.

Ambulance Handbook on the Principles of First Aid to the Injured. By GEORGE THOS. BEATSON, B.A. Cantab., M.D. Edin., Assistant Surgeon to the Western Infirmary, Glasgow, and Assistant to the Regius Professor of Surgery in the University of Glasgow. Glasgow: St. Andrew's Ambulance Association. 1891.—This work mainly differs from the several handbooks already published in the fact of the various subjects being treated at greater length and in a more interesting way than is usually done. The book contains the gist of the lectures its author was in the habit of delivering at one time for the Association. The plan adopted is to give a short account of the anatomy and physiology of each set of organs or systems in the body, and immediately afterwards to treat of their affections and injuries with the appropriate first aid. The book is liberally illustrated, many of the illustrations having been expressly prepared for it, while others have been taken from recognised works on anatomy, physiology, and surgery. The subjects are clearly and fully discussed, technical and medical terms being avoided as far as possible, so as to afford the reader an intelligent knowledge of how to act in the emergencies of every-day life. It is really much more difficult to write a good, judicious book of this kind than is commonly supposed; but we think the author has succeeded, and as any profits arising from its sale are to be devoted to the objects of the St. Andrew's Ambulance Association, we hope it may reap some pecuniary advantage from the publication. We may at the same time briefly allude to the general work of the Association itself. From its report for the year from June 1st, 1890, to May 31st, 1891, we gather that it has twenty-seven centres, that 135 classes and 4180 pupils have been trained during the year, and that the total number of patients conveyed in waggons since the formation of the Association has been upwards of 10,000. The waggons (fourteen in number) are at the call of any person, by day or night, free of all cost and responsibility, and in the principal centres they are in charge of a trained attendant. A total of 34,486 pupils have been trained at this Association since its formation in 1882.

The Age of the Domestic Animals; being a Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog, and Pig. By R. S. HUIDEKOPER, M.D. Philadelphia: F. A. Davis. 1891.—Some of the domesticated animals hold such a high place in our social economy, that everything pertaining to them nowadays receives close attention and study. The means whereby their age can be told with something like certainty, has for many years been a subject that has been dealt with by veterinarians and others, in this country and abroad, in books and pamphlets, so that its literature is somewhat extensive. The latest addition to the list is perhaps the most complete and reliable guide yet presented; as Dr. Huidekoper (who is a professor in the American Veterinary College, New York) has largely availed himself of information contained in the works of other writers, and, with what his own experience and observation have endowed him, has produced a treatise that is likely to be accepted as a standard book of reference for some time to come. The age of the animals enumerated is judged by their dentition, the horns of the ox—when it has any—being also considered indicative of the number of years; those of the sheep are not so valuable in this respect. Of course, a knowledge of the age of the horse is of far more importance than is the case with the other animals; as from its earliest days up to its latest it is necessary in all breeds, but more especially in the higher bred and most valuable, to be able to give an opinion as to how old it is; and, fortunately, domestication and civilisation have had less effect on the teeth of the horse than they have had on those of the ox, but more especially those of the sheep and pig. So that from a few months old, up to twenty, twenty-five, or even thirty years of age, its teeth tell a tale with more or less fidelity, but with most reliability up to ten or twelve years. The ox comes next, but it is not allowed to live so long. Then comes the ovine race, still shorter lived, and, owing to the precocity of the finer breeds, the teeth are not such a good criterion of age. The age of the pig is not of much importance, as it goes to the butcher early, and a knowledge of its dentition is only essential in exhibitions, where the judges have to determine how old the exhibits are. But in none of the domesticated animals are the teeth less reliable; for high breeding has exercised a wonderful influence in the early development of the teeth, and disputes as to age have, in consequence, been more frequent with this species than any other. The author's descriptions of the teeth and their development at different periods are good, and we believe accurate, and their value is much enhanced by numerous woodcuts, which show the result of growth and wear year by year. A concluding chapter on the teeth of man as an evidence of age, concludes a very instructive and useful book, which we feel certain will be appreciated by veterinary surgeons, anatomists, and agriculturists.

An Index of Diseases and their Treatment. By THOMAS HAWKES TANNER, M.D., F.L.S. Fourth Edition, revised by PERCY BOULTON, M.D., M.R.C.P. Lond. London: Henry Renshaw. 1891.—This book, which in its earlier editions enjoyed great popularity, has been thoroughly revised and brought up to date by Dr. Percy Boulton, who has certainly bestowed much pains on the task. It is no easy matter to condense the leading facts of diseases and their treatment within a small compass such as this, and yet the amount of information, particularly as regards treatment, is in excess of what is to be found in many a more ambitious work. Indeed, the chief value of the "Index" rests in the therapeutic hints, which may prove of great service to the practitioner, aiding his resources in times of doubt and difficulty. The very extensive appendix of formulæ, with which are included hints as to climate

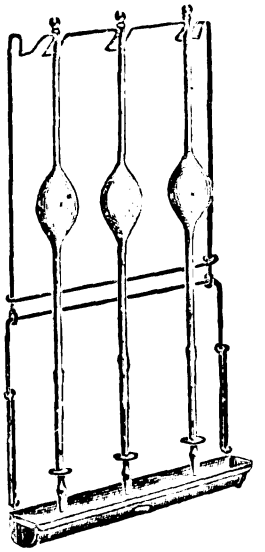
Digitized by Google

and baths, constitute a marked feature of a book which is thoroughly practical and reliable.

An Introduction to Chemical Theory. By ALEXANDER SCOTT, M.A., D.Sc. London and Edinburgh: Adam and Charles Black.—An excellent little manual this, and one admirably fitted to serve as a companion to the practical study of the science. It has long been a moot question amongst teachers as to whether it is better or not to discuss the theoretical portion of chemistry before practical work is entered upon. As a rule the chapters devoted to theory in the average text-book are but few, and this subject in consequence seldom receives the attention it demands. Dr. Scott hopes that this small book may to some extent make up for this defect, and lead, on the part of those using it, to the desire for more knowledge of this most interesting branch of the science. The object for which the book was written is therefore a worthy one, and the subject matter is dealt with in such a way that there is every chance of the hope being realised, if only the work is placed in the hands of the intelligent student.

Dictionary of National Biography. Vol. XXIX. (Inglis—John). London: Smith, Elder, and Co.—The new volume of this excellent dictionary is marked by the care with which each of the biographies it contains has been dealt with by those authors to whom they have been entrusted, and by the manifestly judicious manner in which each subject has been proportioned. The usefulness, fulness, and general accuracy of this work become more and more apparent as its progress continues. It is a classic work of reference as such, without any compeer in English or perhaps in any other language. It is impossible to go through the contents of this volume without being impressed by its intrinsic qualifications in this respect. It affords an almost complete history of Scotland during the period of the Jameses, and the articles on James I. and James II. of England amply repay perusal. Amongst literary men we may note the name of Francis Jeffrey with the history of the initiation of the *Edinburgh Review*, and a very wise criticism of this autocrat of critics. *Apropos* of the episode at Chalk Farm, when Jeffrey and Moore met in mortal combat, which has been immortalised in "English Bards and Scotch Reviewers," the editor states that Lord Byron has "erroneously given the 'leadless pistol' to Moore." This is not accurate. The kilted Caledonian goddess who presided over the destinies of Jeffrey—

> "From either pistol snatched the vengeful lead,
> And straight restored it to her favourite's head."



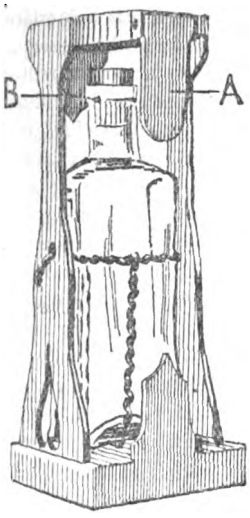
In the footnote relating to the incident, Byron says that when the weapons were examined "the balls of the pistols, like the courage of the combatants, were found to have evaporated." And again, towards the end of the poem, he declares that he had ceased to be alarmed "by Jeffrey's harmless pistol." In the light of these extracts an explanation of giving the "leadless pistol" to Moore might prove acceptable. The life and struggles and work of Douglas Jerrold afford interesting matter for consideration, and a valuable stimulus to those who would penetrate into the literature of that interesting period. A sketch of Jerrold's accomplished son is also given, along with a list of the works which came from his pen. Among the medical worthies, the name of Edward Jenner, discoverer of vaccination (1749-1823), is the first that occurs on opening this volume, and the outstanding facts of his life and works are compiled with judicious care by Dr. Norman Moore. Sir Paul Jodrell, M.D., and Dr. John Jebb (1736-1786), Sir Richard and Samuel Jebb, are also noted in the present volume. A good biographical description is given of Dr. Robert James, the author of a theory of fever and its treatment. His treatment consisted in administering the famous powder which still bears his name, and for which he took out a patent in the year 1746. Its constituents were phosphate of lime and oxide of antimony, resembling the antimony powder of the present B.P. This is the powder which is reputed to have killed Goldsmith. It is historical also in having been prescribed for George III. in 1788. It was Dr. James of whom Dr. Samuel Johnson said, "No man brings more mind to his profession. Dr. Robert Jackson, Inspector-General of Hospitals, who was famous in many ways, has an interesting notice in this volume. He manifested his contempt for the monopolists of the Army Medical Service of his period and for the corrupt administration of the old Army Medical Board by applying his gold-headed cane forcibly to the shoulders of his superior officer, an offence against discipline for which he suffered six months' imprisonment. Notwithstanding this, however, he afterwards became Medical Director in the West Indies and Inspector-General of Army Hospitals. The amount of interesting anecdote and history contained in the work, the evidences of deep and untiring research in its preparation, are so great and so many that the brief notice which our space permits does but scant justice to the labours of those who are responsible for its success.

Repetitorium der Chemie. Von Dr. CARL ARNOLD. Hamburg und Leipzig: Leopold Voss.—A text-book of this kind in our own language would be eminently useful to students of medicine. It deals with both inorganic and organic chemistry in a compass of not more than an inch between the covers, without sacrificing any material that is essential. The index is in its way a lexicon; it consists of no less than fifty out of a total of 612 pages, and is certainly most complete.

New Inventions.

REYNOLDS' "ENEMA RACK."

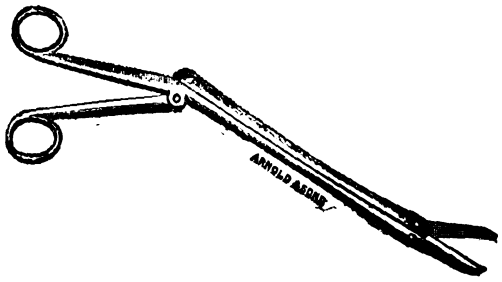
MESSRS. REYNOLDS AND BRANSON of Leeds have sent us one of their new racks, not made for the storage of enemata, as might be supposed from the name, but for the better care of the syringes usually employed for the purpose of administering them. It is adapted for the ordinary ball rubber syringes, which are suspended on it at full length, and any fluid which drips from them is received in a trough below. The racks are adjustable in length by a slide, and fold up for portability. The cost is small, and the advantages to be obtained from their use considerable—especially in hospitals, where so many syringes, either for the administration of enemata or for dressing of wounds, are required. They could easily be fitted with a cover to keep off the dust.



POISON BOTTLE-STAND.

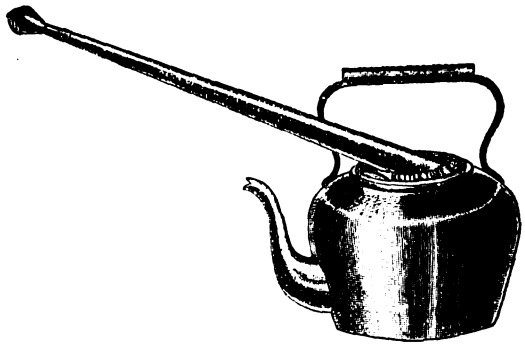
THE problem of enclosing poisons in such a manner that they cannot in any circumstances be administered in mistake for harmless drugs is one that has from time to time exercised the ingenuity of many inventive minds.

Digitized by Google



Mr. Z. Mennell, M.R.C.S., is the latest solver of the problem, whose poison bottle-holder is illustrated in the accompanying sketch. His plan is to provide a simple wooden frame, within which the bottle for containing poison swings in a sort of sling made of twisted wire. The bottle, when in position, as shown in the drawing, is prevented from swinging round so as to render its contents accessible, even if the frame be tilted on one side, by the two stops marked A and B in the drawing—one being placed on the front and the other on the back of the frame, in such positions that the neck of the bottle cannot pass them in either direction. It is therefore impossible for the bottle to be taken up and its contents poured out in mistake. But if it be desired this latter procedure is easily accomplished, for the stop marked A is not rigidly fixed, but is hinged to the frame at its upper part; and although the hinge does not permit it to open outward, it does allow of its being closed up against and underneath the top of the frame by the mere pressure of the finger or thumb. The stop can thus be put out of action, and the bottle swung round to be uncorked or withdrawn. When replaced in its sling, or permitted to swing to rest, the bottle automatically assumes the position shown in the drawing, and of course the hinged stop A offers no obstacle to the swinging in of the bottle neck; although by falling into the position shown as soon as the bottle mouth has passed, it automatically blocks the return, and locks the bottle in its position of safety. The stop shown in the front of the drawing at the foot of the holder is a counterpart of the stop B. The holder is simple, efficient, and inexpensive. It is made in various sizes, and can be used with bottles of the most various shapes. Its designer has very happily avoided the faults of insufficient protection on the one hand, and of over-elaboration on the other. Its use would, in our opinion, be well calculated to prevent the very serious mistakes against which it is intended to provide.

NASAL SCISSORS.



I WAS surprised that scissors such as those shown in the accompanying illustration were not to be obtained of the London instrument makers—at least Messrs. Arnold and Son inquired for me, but could not hear of any having been made. They resemble the ordinary crocodile nasal forceps, but have scissor instead of forceps blades. A glance at the illustration will at once explain their structure and action. They are of use in the division of adhesions across the nasal chambers, in the removal of localised hypertrophies, and in many other intra-nasal operations. They are made by Messrs. Arnold and Son, West Smithfield.

W. J. WALSHAM.

VAPORISING KETTLE TUBE.

MR. ELLIS of Neasden has patented a tube which he claims to be capable of affixing to any ordinary kettle at a moment's notice, thereby converting it into a vapour distributor. It is simple and cheap, and in district nursing it will be found most useful in some pulmonary complaints. The apparatus cannot get out of order, is not cumbersome, and is within the reach of everybody.

CLARKE'S "FAIRY" COMBINATION LAMP.

CLARKE'S "Fairy" Combination Lamp and Food Warmer will be found very useful in the sick room. It is fitted up in a light and elegant frame, in which is placed one of Clarke's "Fairy" lights, set in a glass vessel and protected by a glass shade. The water is soon heated, and maintained at an almost uniform temperature. The little earthenware pan is then placed in the warm water, and its contents are thus kept hot by moist heat. Moreover, where a moist atmosphere is required in the neighbourhood of the patient the food pan can be replaced in the water by an inhaler. Its lightness and compactness, together with its general usefulness, will cause it to be much prized by medical men, by nurses, and by the general public in times when its employment is called for.

SCARLET FEVER IN PUBLIC CONVEYANCES.—An employé of the Manchester, Sheffield, and Lincolnshire Railway Company was fined five shillings for conveying in a railway carriage the dead body of a child who had died of scarlet fever, without having properly notified the fact to the railway company. The magistrates commented on the danger to the public of such a practice.

ANATOMICAL SOCIETY OF GREAT BRITAIN AND IRELAND.—The second quarterly meeting of the session will be held on Monday, Feb. 22nd, at 4 30 P.M., at the library of St. Thomas's Hospital Medical School, Albert Embankment, S.E., Professor W. Turner, F.R.S., in the chair. Papers will be read by Professor Sir W. Turner, on "The Cerebral Hemispheres of Ornithorhynchus Paradoxus;" Professor Sherington, "Note on the Nerve Supply of the Hind Limb of Macacus Rhœsus"; Mr. David Hepburn, "Note on an Abnormal Condition of the Shoulder-joint"; Mr. F. G. Parsons, "Some Points in the Myology of Rodents"; Mr. J. Bland Sutton, "Sections of the 'Velvet' from Stags' Antlers, showing Sebaceous Glands"; Professor W. Anderson, "On the Delimitation of the Regions of the Abdomen"; Mr. F. C. Abbott, (*a*) "A Right Aortic Arch, with Abnormal Arrangement of the Vessels; (*b*) Pulmonary Valve with Four Cusps."

THE LANCET.

LONDON: SATURDAY, FEBRUARY 13, 1892.

THE manner in which the teachings of experience are found to harmonise with newly made scientific observations and the doctrines that are based on them has seldom been more convincingly illustrated than in the series of papers which we have recently published from the pen of Dr. G. SIMS WOODHEAD. These papers contain the latest information concerning investigations upon the intimate working of the organism in reference more particularly to its powers of reaction against disease and injury. We have in them the declaration of principles which carry forward the great generalisation of "cellular" pathology to a point not dreamt of when the principles of that doctrine were first enunciated, for owing to the marvellous insight into morbific agencies gained by the developments of bacteriology the whole aspect of pathology has been changed since VIRCHOW first showed the importance of regarding cell life as the basis of all morbid change. It is of course quite possible that to phagocytosis, which now holds the field, may be attributed a higher function than it can rightly claim; but it must be confessed that a process which has been shown to operate throughout the animal kingdom, which is in point of fact the attribute of the primal protoplasm from which all animal life proceeds, must play a great part in the human economy. It is concerned with normal as well as with perverted function, and it is a conception which may be applied to boundless extent in either of these directions. Moreover, as Dr. WOODHEAD especially showed, the doctrine, supported by so many laboratory observations, has a direct and important bearing upon the art of healing. No one can rise from the perusal of these papers without feeling vastly enlightened as to some of the most familiar facts of disease, for which heretofore no satisfactory explanation has been afforded.

It was time that attention should be turned to the powers of the organism to resist the inroads of disease. We have been surfeited with bacteriological discoveries, and these have followed so quickly one upon another, that there has been a tendency to regard them as in themselves solving the problems of pathology; whereas the fact has been that these discoveries have only added to the mysteries yet to be unfolded; and the study of the effects of bacterial action upon the infected organism, as well as of the nature of the resistance afforded by the latter to the inroads of the zymotic agents, has accordingly become a necessity. The behaviour of leucocytes to foreign matter in contact with them, which is strictly analogous to the properties possessed by the protoplasmic amœba, and the part thereby played by these elements in the removal of dead or useless parts, has led almost imperceptibly to the wider conception of their antagonism to noxious agents introduced from without. But the reason why they exercise this protective power, and the conditions necessary for them to evince it to the full, are problems still *sub judice*, which will require very careful and detailed consideration. Naturally, much of the argument is at the present stage hypothetical, and that there is room for alternative theories is made evident in Dr. WOODHEAD'S articles. The facts of inflammation and repair can, however, be shown to harmonise precisely with the theory (as it must, we suppose, still be provisionally termed) of phagocytosis; and the causes of failure to overcome the intruding agents must be sought in the lack of the necessary stimulation required to evoke the latent properties of the cells, or in the presence of some powerful depressing influence which inhibits their powers of action. A point of much interest is that of erysipelas, where the inflammatory zone, in which the migrant leucocytes destroy the streptococci, does not overtake the advancing line of the latter; and the practical suggestion to excite inflammatory reaction in front of the invading organisms so as to check their progress has, we are told, been of real service. Herein we have a direct therapeutical gain deduced from a single observation in the laboratory. It is, however, in its bearings upon the general principles of surgery that the new teaching appears of special value. We commend the powerful testimony adduced by Dr. WOODHEAD in regard to the utility of absolute antisepticism in surgery, and the cognate matters of practical detail, to the earnest attention of all surgeons. At the same time, he does well to remind us that the dangers of sepsis are not limited to external contamination, and that lowered states of vitality, which impair the power of resistance to the invasion of organisms from the mucous channels or an imperfect state of the excretory functions may render the body vulnerable from another side.

It must be especially gratifying to Professor VIRCHOW to note how the pendulum of modern research is swinging back to the position indicated by his labours a generation ago in the recognition of the paramount share taken by the connective-tissue cells in the formation of new tissue and in metabolism. The leucocyte, according to present day teaching, has a great part to play in the protection of the organism from invasion of foreign material and in its removal from the body; but beyond that it has comparatively little else to do. It, as it were, clears the ground for the fresh formative processes which spring out of proliferation of the fixed cells and are intended to repair the injury caused by the elements that have been got rid of by means of inflammation and suppuration. It will have been observed that from the consideration of phagocytosis and all it implies, Dr. WOODHEAD passed on to allude to some of the practical results accruing from researches upon blood coagulation, and on the functions of the nervous system. These have their place—a very notable one—in modern science and practice; but undoubtedly the greatest achievements are those which formed the groundwork of his papers, since it is through them that we are enabled not only to afford satisfactory explanations of the pathology of infective diseases, but also to discover the most rational methods of coping with them.

"INSTINCTIVE Criminality, its True Character and Rational Treatment," is the expanded title of a paper read by Dr. S. A. K. STRAHAN, barrister-at-law, before

Digitized by Google

the Anthropological Section of the British Association at Cardiff, under the presidency of Professor MAX MÜLLER, on Aug. 25th, 1891. It has since been published in pamphlet form, with prefatory note and appendix, giving cases illustrative of the remarks contained in the text. The opening sentences of the former give a good insight into the object of the writer in bringing this subject forward. "It is so much easier to 'let well alone' than to undergo all the worry and turmoil of reorganisation, that not infrequently ill also is left alone long after it has been recognised as such, not so much from any desire to perpetuate evil or do injustice as from the apathy engendered by the natural desire for 'a quiet life.'" The author proceeds to remark how liable reformers are to ridicule, and even to abuse; and this being so, "it follows that when a proposal embodying sweeping and radical changes in principles which have gone unquestioned for centuries is received with respectful attention and critical consideration, the promoter thereof is justified in assuming that his proposal is timely, and that the public feel some change to be necessary in the direction in which he has pointed." This is the pleasing position in which the author tells us he finds himself, his suggestions as to the proper and different treatment of habitual criminals from that to which they are now subjected having been well received. Dr. STRAHAN undoubtedly deserves much credit for having attempted to put together facts which have been painfully prominent of late, and for making suggestions which must have occurred to those who give a thought sometimes to that other half of the world of which the one half knows so little. It is really lamentable to think how apathetic the public have become to the reports of women being brought before the magistrate for the two-hundredth time, and of both men and women spending a considerable proportion of their lives in prison and in penal servitude. All honour to those who try to remove this apathy; but caution is needed to avoid the opposite extreme.

In his definition of "instinctive criminals," Dr. STRAHAN omits those whose crime has arisen from passion, poverty, or temptation, or even resulted from bad example and associations alone. In the term he only comprises those individuals who take to anti-social ways by instinct or nature, and who murder, steal, lie, and cheat, not because they are impelled to do so by force of adverse circumstances, but "because they are drawn to such a course by an instinct which is born in them, which is too strong to be resisted by their weak volitional power had they the desire to resist, which they have not." There is some truth in this, and for want of an English word the Yankee expression "cussedness" might be suggested. But when Dr. STRAHAN gives this class as comprising "fully two-thirds of our whole criminal population, including offenders of all grades, from the murderer down to the petty thief," we must take exception to this as an exaggeration. Probably 5 per cent. would be a nearer approach to the truth. Still more must objection be taken to the next statement, "To this class also belongs a still larger proportion of prostitutes and habitual drunkards, who, although not criminals in the eye of the law, are anti-social in their instincts. The prostitute ranks with the petty offender of the male sex, she bears all the well marked signs of degeneration found in male thieves, swindlers, and vagabonds, and her existence accounts to a certain extent for the large excess of male over female criminals. It is common in degenerate families to find that while the sons take to crime the daughters take to prostitution." How incorrect this is must be obvious to all who have to deal with prostitutes and habitual drunkards. Among the former vanity, love of dress and idleness are the causes of their fall more than any instinctive criminality, which will only account for a very small proportion. There is an instinctive desire to penetrate mysteries which lead many to their ruin, but it is not this to which the author alludes. With regard to habitual drunkards many of them have lived up to adult or even middle life in perfect sobriety and free from any criminal instinct. Many owe it to the circumstances in which they live and their surroundings. It is much more probable that two-thirds or more of prostitutes and drunkards owe their unhappy position to these causes than to any anti-social instincts. The daily experience of those medical practitioners whose practice has brought them in contact with the poor, or even the criminal classes, has shown them that even the most hardened criminal has his better nature, which will show itself at times. And the object of all laws and penalties must be to teach people to strive with their worse nature and to overcome it. To make pets of criminals in the manner so graphically described by the late CHARLES DICKENS in "David Copperfield," to have the Uriah Heaps and Littimers made interesting subjects of study to admiring visitors is a sure way of keeping them in their criminal career.

Now, as regards insanity, which Dr. STRAHAN declares to prevail very highly among criminals, even to the extent of being forty times that of the average citizen, it is true that prison life favours this unless carefully watched, and the more highly strung organisations are subject to it rather than the dull, instinctive criminal. Besides, this fact, which must be well known to the classes whence "gaol-birds" are derived, ought to be an additional deterrent, which it does not appear to be. To risk losing one's reason as well as one's liberty for some paltry temporary gain ought to act more powerfully than a dread of the "cat."

Suicide is next advanced by the author as a symptom of family degeneration as positive and grave as insanity itself. He shows by careful calculations that suicide is more than ten times as common among our local prison population than among the general population, and nearly five times more common among the inmates of our prisons than among the inmates of our lunatic asylums. Proceeding further, he finds that suicide is about twenty-four times more commonly a cause of death among those who die in our prisons than among those who die outside them. "Could anything speak more eloquently of the wretchedly low level at which the inmates of our prisons have arrived. Weak and ill-developed in body and mind, they are unable to contend successfully against their fellows for an existence, and instinctively they fly for relief to 'nature's cure.'" But is not this opposed to history and fact? In pagan times, and where the pagan spirit now lives, suicide was the refuge, and still is, of men of more than average brain power. The "low, cunning man" is

Digitized by Google

not the one usually found to commit suicide. Many of the suicides occur from misadventure in malingerers.

Passing on to the physical side of the criminal classes, Dr. STRAHAN remarks that all who have examined the inmates of our prisons and penal establishments agree that they represent a decaying race. "It must be admitted, then, that the criminal, as met with in our prisons, is a degenerate and morbid specimen of the human family." Granted; but is this a special mark of instinctive criminals? All sin destroys. Out of prison we have deaths from "excessive drinking," from "natural disease aggravated or accelerated by drink," from "delirium tremens"—from a host of secondary causes where drink is the primary one. Again, though syphilis is seldom the immediate cause of death, it is the primary cause in many more cases than is generally known, and this quite apart from gaols or criminals. This summary view of all criminals is an assumption, and contrary to fact, since it assumes that all are instinctive criminals.

The physical description of the criminal is thus given by the author. "The criminal is very closely related to the insane, especially the congenital insane, and personally he bears a strong family likeness to his near relative the idiot. In the criminal we find small, over-large, and ill-shapen heads, paralyses, squints, asymmetrical faces; deformed, shrunken, ill-developed bodies, abnormal conditions of the genital organs, large heavy jaws, outstanding ears, and a restless, animal-like or brutal expression, all of which are common characters amongst the inmates of our idiot and imbecile asylums; and as there is no beauty to be found among the inmates of such asylums, neither is there any to be discovered in our prisons, proving how well founded is that instinctive feeling of repulsion excited by the sight of the ill-favoured and deformed." All this is true of instinctive, but not of criminals in general, and yet the description is made to apply to all criminals.

It is only natural that the author should dwell upon the subject of hereditary influence, the drunkenness of parents, as the cause of crime in the children, &c. But this applies to all. Who can tell its limits? Pushed to its logical conclusion it makes everyone irresponsible. Passing on to the important question of treatment, Dr. STRAHAN first shows how very small a deterrent effect prison treatment has upon offenders. Of a total of 150,559 prisoners received into local prisons during the year ending March 31st, 1891, no less than 58·57 per cent. had been convicted before; 26·78 per cent. had been three times previously convicted, while a percentage of 15·32 had lists of previous convictions varying from eight to two hundred. "The system of treatment which," he says, "I would propose should take the place of the present would be prolonged incarceration upon an indefinite sentence in an industrial penitentiary. Every judge of assize, recorder, and stipendiary magistrate should be empowered when he thought fit to send any person convicted before his court to an indefinite term of incarceration in such penitentiary, provided at least three previous convictions could be proved. In this institution the plank bed and solitary confinement would be unknown. In the place of such treatment every effort would be made to improve the criminal so far as possible morally, physically, and intellectually, and from this place he would be set free on parole, only when it was thought that his anti social instincts had become sufficiently blunted to enable him to mix with society with safety.' There is much common sense in this. Many of the unfortunate women who have been convicted of drunkenness and riotous or disorderly behaviour, including window smashing for the hundredth time, are women whose only real home is the gaol. Taken from their wretched haunts, compelled to live a sober and comparatively healthy life for the short—too short—term of imprisonment, their health improves, and they leave in a better state than they entered, only to return to their old habits. The same remark applies in a modified form to the older and more hardened prostitutes and to many men of the thieving classes. Dr. STRAHAN'S conclusions are good, though not based upon entirely correct premisses. Starting with "instinctive criminals," he passes on to include all prisoners. The degeneration of the individual once having the *mens sana in corpore sano* is entirely neglected and assumed to be the result of heredity. The omission of the corrupting influences of vice on healthy organisations—in fact, a devolution of the race—is necessitated by the natural desire to make out a case. For "practical politics" the fact is sufficiently glaring, and calls loudly for amendment—viz, that "incorrigibles" should be kept for considerable periods in "industrial homes." There are many other points of interest in Dr. STRAHAN'S paper which have been of necessity passed over or briefly noticed, but the more important have been dealt with. The instinctive heredity theory and many side issues, which are all open to question, are not necessary for the treatment suggested.

SPRING is not only the most trying season to health at home, but it is the time of the year for which it is difficult to select any perfectly unobjectionable sanatorium. We have summer and autumn resorts which leave little to be desired, and the list of admirable winter sanatoria, fulfilling the most various and diversified indications, is a very long one, and is constantly increasing. But spring remains the intractable season, and the reason is not difficult to assign. The reason is that at this time the hot stations well to the south, such as Egypt, Algeria, and Morocco, become too warm for comfort, while it is yet too early for the invalid to contemplate a return home. Under these circumstances we should naturally turn to those sanatoria which are intermediate in situation between Africa and the British Islands; such resorts, namely, as those on the northern shore of the Mediterranean—the Riviera, Castellamare, Sorrento, Malaga; or some of the Mediterranean islands, especially Sicily and Corsica; or such resorts as Pau, Arcachon, or Biarritz. Unfortunately none of these resorts is altogether unobjectionable in such months as April and May, though much depends upon season; and a beautiful spring, comparative freedom from cutting winds, and sudden fluctuations of temperature may occasionally be experienced at some of the places indicated, but such good fortune cannot be reckoned upon with any confidence. In fact, throughout Europe spring is a changeful and treacherous season. The reason would appear to be that at this season the westerly wind currents from the Atlantic, which dominate the climate of

Digitized by Google

Western Europe during the greater part of the year, give way to a downflow of dry and cold winds from the bleak plateaus of Central Asia. Hence, mildness equability and calm, which characterise so many favourite resorts during a large part of the winter, are hardly to be expected during spring.

These remarks apply with full force to the Mediterranean basin, around which are grouped not only so many places famous in history, but so many of our most popular and valuable health resorts. The spring climate of the Mediterranean is characterised generally by high winds, sudden gales, and irregular fluctuations of temperature. In addition to the considerations adduced above, the Mediterranean probably owes the changefulness of its climate in spring in no small measure to the fact that at this season the sirocco begins to blow, and comes in conflict with the westerly Atlantic winds and the cold easterly and north-easterly winds from Central Asia. With this conflict of winds from various quarters, differing as they do so much not only in temperature but in hygrometric condition, and all converging on the Mediterranean basin, it is not surprising that sudden storms and rapid changes should be frequent.

The spring winds prevalent on the Riviera are well known to constitute the most serious drawback to that delightful region. The most obnoxious of these is the too familiar mistral—a cold and dry north-west wind, of which the old rhyme says, not untruly:

> "Le Parlement, le mistral, et la Durance
> Sont les trois fléaux de la Provence."

The mistral blows off and on during the winter, but not frequently and with only moderate force; but as spring draws on, its visitations become more frequent and it blows with greatly increasing violence. March is usually the worst month. This wind generally blows for two or three or more days consecutively, falling at sundown and rising again the following forenoon. It is of a very parching character and is often accompanied by bright clear skies. The mistral is mostly felt in the western Riviera, and gets milder as we go east. It is very severe at Marseilles and Hyères, serious at Cannes and Nice, much less felt at Mentone and San Remo, and comparatively insignificant at the east of these points. The east wind on the Riviera is less frequent and less violent during spring than the mistral. The north-east wind is one of the great drawbacks of the climate of Genoa. The sirocco is the rain-bearing wind of this region, and is comparatively common in spring. Its depressing and debilitating effects are well known.

Of the places which we have enumerated as intermediate between Africa and the home country, there are several that possess a more stable spring climate and one less vexed by troublesome winds than the Riviera. Such is Malaga, which possesses one of the best climates in Europe, but is, unfortunately, a dull place, with few attractions for invalids; such is Ajaccio, a resort still comparatively undeveloped, but with many great advantages, and with probably a future before it; such is Arcachon, one of the best of the mildly sedative resorts. These sanatoria have not only great merits as winter resorts, but are worthy of special attention as refuges from the disagreeable features characteristic of so many other places during spring. Malaga and Arcachon are old favourites and well known, Ajaccio is a newer claimant for attention, and seems to possess many admirable features. Spring winds are not only very trying and disagreeable in themselves, but in most places they are accompanied by clouds of dust, which are unpleasant to all, and especially hurtful to *poitrinaires*.

We have said nothing regarding the spring climate of the southern Mediterranean shore, as invalids only exceptionally prolong their stay in Egypt, Algeria, or Morocco beyond April. Those who have wintered in these regions should be in no undue haste to exchange the assured sunshine and warmth of the southern Mediterranean shore for the sharp winds and changefulness prevalent at this season on the northern shore. A little discomfort from heat is a less evil than running the risk of fatal chills.

Spring is the great season of the fatalities of the travelling invalid, who so often weathers the winter successfully but suffers serious relapse during the spring months. This unfortunate result is no doubt partly due to the inherent treacherousness of the spring season, but also in large measure to the indiscretions of invalids. In many of the resorts mentioned the warm sunshine and bright skies common in spring entrap the unwary into disregard of the dangers lurking in the cold winds. Hence arise colds, chills, and intercurrent inflammations, which so commonly hasten the progress of chronic disease or precipitate a fatal issue.

MUCH alarm has been occasioned by the reported reappearance of the very infectious foot-and-mouth disease of bovines, which was discovered among some cattle that had come from Denmark, and were exposed for sale in the Metropolitan Cattle Market at Islington on the 4th inst. There might exist some doubt as to whether it really was the malady known to veterinarians as eczema epizootica, and which had been allowed for so long to play havoc, without let or hindrance, among our flocks and herds, but was finally stamped out some six years ago, for, according to the Danish authorities, the disease is not present in Denmark, and since its reported appearance on the 4th inst., special inquiry has been made in the district from which the animals were exported, without finding a trace of the affection. And it is to be noted that this is, of all the infectious diseases of animals, the one which can be most readily detected and has the shortest incubation period. So it is not at all improbable that this has been a false alarm; for if foot-and-mouth disease is non-existent in Denmark, and the animals exposed for sale at the Islington Cattle Market had not come into contact with infected animals—cattle, sheep, or pigs—during transit to this country, they could not have it. All experience proves that it no more arises spontaneously than does any other of the specific fevers; and perhaps the most convincing evidence in this direction is the circumstance that the United Kingdom has been free from it for six years, merely because, when extinguished, it has been kept rigidly excluded by forbidding the entrance of cattle from infected regions. These, so far as we know, are chiefly European countries and India. The malady is unknown in Australasia and the United States of America, never having been allowed to obtain a footing in these

Digitized by Google

quarters of the globe, though it has been carried to each of them on at least one occasion. In the States there was an outbreak last year of a disorder not unlike this; but it was not infectious, and was probably due to some irritant on the pastures.

It is somewhat remarkable that, though observed and described on the continent of Europe for more than two hundred years, the disease did not reach this country until 1838, when it spread almost like wildfire everywhere, attacking cattle, sheep, pigs, and poultry, and even people who handled the animals or consumed the milk of sick cows. It caused much consternation as a new disease which inflicted great damage, though it was not particularly fatal, and for many years nothing was done to check its prevalence; as it was supposed to be due to that "something in the air" which was always invoked when the etiology of such plagues was not understood. The success that attended the extinction of the deadly cattle plague in 1866, drew attention to the great relief agriculture would experience were similar measures applied to this foot-and-mouth disorder. Unfortunately, however, the steps taken by the Government were altogether inadequate to combat such an easily dealt with epizootic malady; almost everything being left in the hands of local authorities, who used their own discretion in applying the measures prescribed, and with the result that after some years' trifling with it, at great cost, it was as rampant as ever. When at last the central authority took the mattter up in earnest, it was not long before the scourge was subdued by the use of the pole-axe, compensation being allowed to owners of diseased and suspected cattle. In 1879 the contagion was extinct, and nothing more was seen of the malady in these islands until October, 1880, when it was again introduced in a cargo of foreign cattle disembarked at Deptford; thence it found its way to the Metropolitan Cattle Market; from there it spread so quickly over the land, that at the commencement of December no fewer than twenty-five counties were invaded. So badly was this invasion controlled that, in 1883, seventy-one counties were scourged by it, the outbreaks being 18,732, and the number of animals attacked 461,145. It was not until 1886 that the three kingdoms had again a clean bill of health, so far as this plague was concerned; but the cost of the negligence which had allowed the contagion of this one importation to escape from Deptford and reign for eight years, was most serious, and can scarcely be estimated. During that period 743,168 animals were reported as affected; and as some of the most competent authorities reckoned that the loss on every animal that did not die or was not slaughtered, could not be less than £3 or £4, the money loss alone to the owners of stock must have been, at the lowest computation, £2,500,000. This immense sum does not include the expense of stamping out, which entailed an enormous slaughter of cattle and consequent compensation; neither is any mention made of the expensive machinery which this process demanded, nor yet the heavy loss incurred by the closing of fairs, the stoppage of movement of cattle, and the embarrassment to the milk and meat trades. For it should not be forgotten that in these visitations it is not only the grazier, breeder, and cattle dealer who suffer—though their collective loss is also a national loss,—but the meat and milk consumers share in the disaster. These commodities become scarcer, and therefore dearer, a matter of much moment to the poorer section of the population; while in this malady there is a chance of the infection being conveyed to those who ingest the uncooked milk. Calves which are being suckled by affected cows often die from gastro-enteritis and it might, therefore, be apprehended that infants and young people incur the risk of similar injury.

Let us hope that, as there is some reason to believe, this is a false alarm; or if it be the real malady, that eight years may not again elapse before it is extinguished. Our agriculture cannot now withstand such shocks as the last one proved itself to be, nor will the public readily forgive such laxity in dealing with a disorder the most easily detected, and most readily suppressed of any that can be controlled by sanitary measures.

Annotations.

"Ne quid nimis."

THE PROPOSED GRESHAM UNIVERSITY.

DURING the past week the Councils of King's and University Colleges, and the representatives of the Medical Colleges (designate) in the proposed Teaching University for London have met, and in each case the change of name has been approved. A joint petition from the two teaching colleges has been sent into the Privy Council praying that the alteration of name may be sanctioned, and a letter expressing their concurrence has also been forwarded by the ten London medical schools. It is hoped that this sanction will immediately be granted, and the Draft Charter will then be laid on the tables of both Houses of Parliament. A reply to the objections made by the authorities of the Victoria University is under consideration, and will be drawn up as soon as the various medical schools have given the necessary authority, and will be sent to members of Parliament with the amended Draft Charter. The medical schools of Birmingham, Bristol, and Sheffield have also drawn up a joint protest, pointing out that injury would be inflicted on them if a new Teaching University for London were established. The reply to this is simple. Either of these schools, if sufficiently equipped, can apply to the Victoria University for incorporation, and thus follow the example of the Yorkshire College of Science at Leeds. Or the science and medical colleges at Birmingham and Bristol may so organise themselves as to form a Midland University, on the lines of the Victoria University, with power to take in other properly established colleges, and so complete the number of Universities that would be sufficient to meet the local demands of England. It is rather too much to ask Parliament not to remedy the grievance of the London medical student because all the provincial schools are not in a position to apply for similar privileges. We do not think the case of the Victoria University or of these medical schools is improved by urging that, because the new University will have a very large proportion of medical representatives on its Council, this body cannot be trusted to maintain the standard of medical degrees, as well as a sufficient standard in arts and science. The opinions of Sir George Young and Mr. Erichsen are not to be taken as representative of the views of a Council not yet formed; they were declared to be merely individual statements, and in no way to be looked on as official.

Digitized by Google

It is not to be expected that the standard of any new University will be fixed as high as that of the existing University in London, which the Royal Commissioners declared to be an "honours" degree; yet that between this and the standard for an "ordinary qualification" there is ample room for a new degree for London medical students must be clear to every member of the profession who recognises the position of the Victoria University itself, of the University of Durham, and of the Scotch Universities.

PARTRIDGE v. THE GENERAL MEDICAL COUNCIL.

MR. PARTRIDGE, before Mr. Justice Denman and a special jury, applied on the 6th inst. for a *mandamus* to order his name to be placed by the General Medical Council in the Dental List, under the Act of 1878. Our readers may remember the chief particulars of Mr. Partridge's case. He held a diploma from the Royal College of Surgeons in Ireland, under condition of not advertising for business. He violated this condition. His excuse for doing so was alleged to be the failure of his sight. The College cancelled his diploma, and the Council in 1886 struck his name off the Register. The Court of Queen's Bench ordered the restoration of his name on the ground that the Council was bound to judge for itself and not merely endorse the action of the Irish College of Surgeons. Thereafter the Council considered the case and determined to remove the name, as it has power to do. The plaintiff contended that the Council had no right to do this. Mr. Justice Denman, after going elaborately into the case, found no evidence of malice against the defendants, and felt bound, though reluctantly, and expressing some sympathy with the plaintiff, to nonsuit him. Judgment was given for the defendants, with costs, but execution was stayed with a view to an appeal. Mr. Justice Denman asked if anything could be done to let the plaintiff off costs, and Mr. Muir Mackenzie, acting for the General Medical Council, promised to convey the judge's remarks to the executive committee of the Council. All who read the report of this case must share with his lordship a pity that the plaintiff should have become blind. And, undoubtedly, this fact gives an element of pathos to an otherwise completely indefensible case. It was in Mr. Partridge's power to have practised dentistry and to acquire a place on the Dentists' Register without any diploma from a medical authority or college. With good taste he preferred to take such a diploma, and so to place himself in relation with, and under the discipline of, one of the Royal Colleges of the profession, which happily tries to enforce its laws against unprofessional and vulgar methods of practice. Unfortunately, he violated these laws and his promise to keep them, in spite of much patience on the part of the College authorities, and indulged, according to the evidence on his own side, in a huge and bold system of advertisement. We cannot see that the affliction of blindness in one of its members is to dissolve the whole system of College discipline and to give him privileges which he had not before. It is satisfactory to find that the judgment of Lord Denman only confirms all previous judgments as to the absolute power of the Council to judge of professional conduct, so long as the Council acts in good faith.

MEDICINE IN SOUTH AUSTRALIA.

AT a commemoration of the University of Adelaide held on Dec. 16th, 1891, Dr. Verco, orator for the year, gave a detailed and interesting account of the rise and progress of medical knowledge in South Australia and of the Adelaide Medical School. The good old times of early settlement, when city consultant and "scrub" doctor made acquaintance daily with the rough and ready circumstances of pioneer practice, are briefly but graphically sketched. So, too, is the history of the Adelaide Hospital, founded first as a temporary structure in 1839, subsequently expanded, and in 1885 affiliated with the University. In this year the latter arose by the aid of funds originally destined for the requirements of a theological institution—Union College. It was at first intended that its modest curriculum, as far as medicine was concerned, should include merely the subjects taught in the first two years of student life. In a very short time, however, a complete course of study was arranged, and now "the production of the medical practitioner is a native industry." The fact that the standard of medical education is sufficiently high is a satisfactory one, and it is attested by the right of registration freely accorded to the colonial degree in this country, and by the acceptance of its associated course of study by the conjoined London Colleges. In face of the nearly universal superabundance of young, but qualified, medical talent, we do not gain much assurance from a statement that in a few years the medical work of the colony will soon be in the hands of its own graduates, the process of immigration being virtually arrested by "native industry." Upon these matters and others of a like sort Dr. Verco dwells with natural satisfaction. After some further observations on the general progress of medical knowledge in recent years, he closes an instructive address with a series of original and somewhat carefully studied remarks on the preservative and curative properties of a healthy and spiritual religion. In these he asserts the existence of a spiritual prophylaxis, a prevention of disease by religion. Anger, excess, and every form of egotism, prone as they are to corrupt the mental state, will, he avers, find in it the means both of prevention and cure, and the surest hope of progressive vitality rests, he maintains, upon obedience to spiritual law.

THE RISKS OF LEATHER WORKERS.

THERE is a process of softening the leather used for saddlery which is very injurious to the health of the workmen engaged in the craft. M. Etienne Ferrand of Lyons has recently brought forward proposals for remedying this evil. After the leather has been tanned, but prior to its being rendered supple and before it is scraped and polished, grease has to be rubbed into the pores. The entire skin before it is cut is heated and thoroughly dried in a stove. The skin is then spread upon a table, and tallow at a temperature of about 250° C. is poured upon the leather. The workmen rub this melted tallow into the pores of the skin. But the tallow when heated to this extent gives off acrid vapours, which irritate the respiratory organs and occasion much suffering to the workmen. This is due to the presence of acroleine in the vapours, produced by the decomposition of the glycerine. The acroleine, when coming in contact with the air, forms acrylic, acetic, and formic acids, and is readily volatile at ordinary temperatures. A few drops of acroleine volatilised in a room will render the atmosphere almost insupportable. For this reason, workshops and factories where leather for saddlery is made are put by the French Legislature in the second category of unwholesome industries. M. Ferrand proposes that, instead of rubbing superheated tallow into the skins by hand labour, the skins should be placed in stoves with tallow maintained just in a state of liquefaction—namely, from 100° to 120° C. No irritating vapours would then be produced. If it was found that the liquid tallow did not sufficiently permeate the skins, the rubbing by hand could be replaced by rollers or other methods of bringing to bear mechanical friction. M. Ferrand touches, however, upon the real difficulty when he suggests that tallow costs 80 c. the kilogramme and leather 3 fr. 50 c. the kilogramme. By the hand process the workmen are able to introduce so much tallow that the grease in the leather

Digitized by Google

represents from 35 to 45 per cent. of the total weight. For doing this the workmen receive a supplementary wage of 3 fr. per day, which, added to their ordinary wage of 5 fr. a day, makes a very considerable difference. Doubtless if some such method as that suggested by M. Ferrand were applied, good leather could be made without any inconvenience or risk to health. But the leather, though equally strong, would not be so heavy, and the workmen would lose their claim to a supplementary wage. Therefore both employers and workmen are opposed to the more wholesome process. M. Ferrand is more likely to be supported by the trade when he urges that in any case there should be, by the side of the workshop where the tallow is rubbed into the leather, a spare room, well warmed and ventilated, where the workmen could seek rest and fresh air between each operation. To this the workmen at least would not object, but the employers would probably complain of the extra expense involved. It seems deplorable that the health of the workmen should be gravely compromised for the sake of increasing the weight of leather by forcing into the pores more grease than is necessary.

"STRANGE DEATH OF A DOMESTIC SERVANT."

AN inquest was recently held at Goring touching the death of Sarah Pearce, aged twenty-one years, a house and parlour maid. From the newspaper report it appears that deceased had complained of feeling unwell for a few days, at the end of which time her mistress found her outside the latter's bedroom door, shivering and clad only in her chemise and stockings. She was put to bed and given some soup. To prevent her further wandering about her room-door was locked. Next morning she was found dead under her bed. Mr. Treharne Symonds, L.S.A., who was called in after the death, said, at the inquest, that he could not form "any possible conjecture as to the cause of death." The jury returned a verdict of "Death from natural causes," with a rider that the girl was neglected by her mistress. If the case is fully and correctly reported in our contemporary, the event shows too clearly that, from whatever cause, the girl was suffering from the delirium of a fatal illness. To our minds it is passing strange that the inquest was not adjourned for a post-mortem examination to be made. We trust the matter will be brought before the Home Secretary, with a view to his considering whether exhumation of the body and an exhaustive inquiry should not be held.

RULES FOR ANTISEPTICS IN OUT-DOOR MATERNITIES.

THE Committee of Management of the General Lying-in Hospital have issued rules for the use of antiseptics, which are meant especially for those practising in out-door maternities. They are to be had for a penny at Vacher and Sons', printers, Westminster. Chiefly they provide for antiseptic powders, consisting of ten grains of corrosive sublimate and one grain of cochineal. They are to be labeled "The Corrosive Sublimate Powders (Poison)." These are, when wanted, to be completely dissolved in a pint of hot water in a clean basin, giving an antiseptic solution of the strength of 1 part in 1000. This solution is to be used thus: The midwife, after thoroughly washing her hands and nails, is to hold them for a full minute in the solution. Sponges are to be kept in for a full minute before use. After labour the external parts are to be washed with the antiseptic solution. A bottle of "corrosive sublimate glycerine (poison"), consisting of two ounces of glycerine in which one grain of corrosive sublimate has been dissolved, is also provided. The fingers are to be dipped in this before making a vaginal examination. Catheters before use are to be plunged in the antiseptic solution for a full minute and then anointed with "corrosive sublimate glycerine." We are glad to see that midwives are not instructed or authorised to use vaginal douches of corrosive sublimate. Where vaginal douches are required they are to dissolve a teaspoonful of the crystals of permanganate of potassium (which they are to carry in an ounce wide-mouthed bottle) in two quarts of hot water at a temperature of 110° F. Rule 11 instructs that the eyes of the child shall be wiped with a clean napkin, and when being washed shall have squeezed over them, the lids being separated, a clean white rag or piece of cotton soaked in the antiseptic solution. The only misgiving we should have is whether it is right to trust such poison in such coarse quantities in the hands of those who can scarcely appreciate their intensity and the risk of accident. The rules might be stated with still more explicitness. Cautions against the use of perchloride douches by midwives should be more expressly stated. Not the least secret of success in antiseptic midwifery is in the homely secret of having absolutely clean hands and nails, with corresponding attention to clothes and instruments. A more elaborate account of antiseptics in obstetric and gynæcological nursing and practice will be found, with directions for use, in Dr. John Shaw's manual.

THE WORKHOUSE INFIRMARY NURSING ASSOCIATION.

THIS Association, which has been engaged for many years in investigating the condition of the inmates of infirmaries and the arrangements in existence for providing a suitable nursing staff for them, have published a report on the country infirmaries. It states that in some of the infirmaries there may be only one nurse responsible for the entire care of the sick of the union, having occasionally as many as forty or fifty cases under her care. It is simply impossible for a nurse to deal adequately with so many patients, and the result is that the care is handed over to the paupers, an account of whose modes of nursing is graphically described in the early pages of "Oliver Twist." Miss Wood, in her report, says "until pauper nursing is banished from our infirmaries these 'disgraces' must be occasionally accepted." We commend in the name of humanity this aspect of the Poor-law to those who are advocating much-desired reforms of it in other directions.

OPERATION FOR JACKSONIAN EPILEPSY.

IN the *American Journal of the Medical Sciences* a case of much interest and importance is related by Dr. Keen and Dr. Mills of Philadelphia. The patient was a young woman of twenty-seven, who for ten years had been subject to fits, at first occurring at considerable intervals, but latterly becoming much more frequent, and with only short periods of freedom. These attacks were at first of the nature of numbness and pricking in the left upper limb, merely sensations, but latterly motor phenomena had been superadded. A typical attack began with a sensation of pricking in the left arm. This was followed by a plaintive cry, and the left arm then became extended at the shoulder. Almost simultaneously the left leg became rigid and the head turned to the right. It is not stated whether the eyes also deviated, but the right arm was affected, becoming flexed at the elbow. Although these attacks occurred sometimes as often as six or seven times in twenty-four hours, there was no paralysis present and no objective sensory changes. An operation was decided upon, and as the centre for the left shoulder seemed to be the focus of irritation, trephining was performed at a point in the skull corresponding to this. The bone was found to be very thick and dense, to be eroded on its inner surface by a small growth

Digitized by Google

starting apparently in the pia mater, involving the dura mater, causing its adherence to the pia mater, and finally pressing upon and eroding the inner table. The growth looked like a hypertrophied Pacchionian body, but was subsequently found to contain sarcomatous elements. It was removed, and stimulation of the cortex by the interrupted current was then resorted to, with a view to localising accurately the centre for movement of the shoulder. This was found quite close to the point where the growth was, and it was excised. The wound was then closed, but on account of its sclerosed condition the bone was not replaced. Healing took place by first intention. Subsequently paralysis, gradually spreading, affected the left arm and leg, causing complete loss of power in those limbs; but it cleared up again in a few days, and no permanent loss of power remained, and no sensory impairment. Unfortunately the attacks did not cease, but they became less severe. The case is an exceedingly important one, and we are glad to have it in such detail. There is a curious omission of any report on the condition of the optic discs—a point which was doubtless investigated. It would also be interesting to know whether, after excision of part of the cortex, touches, which apparently were perceived without difficulty, were correctly localised, especially about the shoulder, and also whether the sense of position of the limb was in any way disturbed. These are points of considerable importance, both practically and theoretically, in all cases in which the cortex has been excised.

SUGGESTED REMEDIES FOR OVER-POPULATION.

INASMUCH as excess in anything is an error, it is doubtless correct enough to speak of the evil of over-population. The due relation which is characteristic of true economy allows no exception among the arrangements connected with domestic food-supply and the increasing demands of hungry children. It is nevertheless a matter for argument whether the significance of this assumed evil has been always rightly understoood. Viewed by themselves, such facts as the prevalence of poverty, the scarcity of employment, and their consequences apparent in close unhealthy homes, overcrowded with young children, are certainly discouraging, and contrast unfavourably with the comfortable independence enjoyed by capable and active individuals and by many childless couples. It is clearly unfair, however, to lay the blame of all this misery upon the process of reproduction. We must remember that physical fruitfulness has marked the career of all strong and prosperous races, and this, too, without the conscious employment of any selective method. By their exertions the world's work has been and is for the most part done, and it would be a mistake to diminish its needful complement of workers. It is true likewise that the evils complained of are in no small degree the outcome of other causes than the mere pressure of numbers. Want of thrift, instruction, and forethought, unequal conditions of labour and capital, overcrowding in certain districts, and the like have quite as much to do with the matter as the size of families. We venture therefore to state our opinion that the evil influence freely attributed to this cause is, to say the least, a still uncertain quantity. As regards the various remedies proposed for its repression, we are no less sceptical. Such artifices as the tolerance of illegitimacy, the discouragement of marriage, and a variety of means advocated and employed, notably in France, for the restriction of pregnancy among the married, are open to serious moral objections, which if unrestrained would ultimately ruin the society created with their assistance. Moreover, they do not allow for any reliable method of selecting the surviving progeny. The feeble and the strong would still grow up together, but there would be fewer of both. No less objectionable, notwithstanding its scientific aspect, is the plan suggested by Dr. W. T. Greene, whose paper on the subject we have received—namely, that an artificial process of selection be instituted according to which the apparently feeble or diseased would be deprived by operation of their genital capacity. Apart from the manifest crudeness of this device, we need not show that it encroaches very far on the sphere of personal right. Again, it could hardly be relied upon as a selective method, so little can we trust to the presage of infancy. We fail, therefore, to find in any of the above-mentioned remedies the real cure for this general overcrowding. It does not follow, however, that we would uphold all presently existing customs. That faults are to be found in our marriage system we do not deny. There is that, for example, which allows of early though mature maternity, and there is the imprudence of marriage without reliable means of sustenance. We would also be foremost in denouncing the culpable recklessness which takes no thought of evident constitutional disabilities, though it is not clear how any Legislature could deal with these matters, while much may be expected of judicious education. In emigration we have a method already much and successfully used for the relief of districts burdened with a surplus population. It is to such natural means, combined with the exercise of ordinary prudence in home life, rather than to any of the readier and more showy panaceas we have touched upon, that we would look for that rational adjustment in vital conditions which all of us desire. But, after all, and under any system, we shall long have among us, though it be in diminishing numbers, the poor as well as the rich.

THE HEALTH OF FLORENCE.

AN Italian correspondent writes: "The Syndic of Florence, from the 1st inst., has ceased to transmit to the Prefect the daily bulletin of cases of influenza, no cases of the disease for some days previously to the 1st having been reported to the municipio. In December and January influenza prevailed, though not in epidemic proportions, and the type throughout, as in Rome, was very mild. Typhoid fever, it may be added, figures very low in the Registrar's returns. During the whole month of January there were in Florence (city and commune) only six cases of death from that cause."

MEDICAL REFEREES AND LIFE ASSURANCE OFFICES.

IN the new edition just published of Mr. Bunyon's book upon the "Law of Life Assurance" there is a reference to the vexed question of medical referees and their fees. The author says that a claim has been made by some members of the medical profession, when applied to as the medical referees of parties proposing insurances on their lives, to the effect that they are entitled to a fee for their certificates, and they remark that to this "no objection can be raised." But he adds that medical practitioners have endeavoured to extend the proposition, adding to it this further term—namely, that they are entitled to receive the fee from the insurance office, and not from their patient, and that in three instances the question has been tried in the county court, the point raised being whether there was any contract on the part of the company to pay the fee, and in every case it has been decided in the negative. They suggest that, by way of preventing misunderstanding, the medical man should reply to the applicant to the effect that without payment he will give no answer, whereupon they opine that the company, if continuing to request the information, would be bound to pay for it. We have no doubt that this is perfectly sound advice, but it occurs to

Digitized by Google

us that there is an alternative course which would in some instances be preferable to that here proposed, and upon which we should be glad to have our author's view. The medical practitioner might write, not to the company, but to his patient, asking whether the company had authority to pledge the patient's credit for the fee. If the patient replied in the affirmative, well and good; the company need not be asked to pay. If the patient repudiated the company's authority to make any application to the medical attendant in his behalf, the company might be safely debited with the fee, since it would be absurd to suppose that the medical certificate would be given free of charge. If the company has no authority to pledge the patient's credit, it must be taken to pledge its own. Such at least is the common sense view of the situation, and we should be much surprised to learn that it is not also the law.

PURE COAL.

MUCH of our English coal is of a somewhat low quality. Not only does it contain slate and other earthy impurities, but also, unfortunately, pyrites, more than one-half of which consists of sulphur. Our coalfields are being worked out with a velocity which produces anxiety in the minds of all who are interested about the future of the country. We cannot afford to waste even the poorest kind of fuel, and the propriety of restricting exportation has repeatedly been urged with powerful arguments. But in the meantime the burning of impure and dirty coal is a source of tribulation to housekeepers and of injury to manufacturers. According to Mr. Percy Bateson, who in December last read a paper to the Liverpool section of the Society of Chemical Industry, the process of Mr. Lührig, which appears to be the latest improvement upon various previous attempts, renders it possible for colliery owners to clean, and to some extent to purify, without great expense, the coal before it is sent away. The system involves a series of operations, in which are included dry separation, breaking, sizing, washing, recovery of sludge, automatic transportation, &c. It is said that the method is already in successful operation in many places, and from a sanitary, no less than from an economic point of view, everyone must hope for its success.

DEATHS UNDER ANÆSTHETICS.

A DEATH occurring while the patient was under the influence of ether is reported from Bath. The patient, a man aged thirty seven, applied for relief for pains which the officer who saw him describes as being symptomatic of "acute dyspepsia;" but the fact that there was a strangulated hernia appears to have been overlooked, although he had suffered from a rupture for two years. However, he was subsequently admitted into the institution, and it was found he was suffering from strangulated hernia, which it was deemed necessary to relieve by operation. The patient was at this time in an extremely prostrate state, vomiting large quantities of black fluid. After consultation he was put under ether, and ten minutes later the operation of herniotomy was commenced. However, two minutes subsequently the condition of the patient became so grave that the operation had to be abandoned and artificial respiration resorted to. The heart beat for an hour and a half after cessation of respiration. The windpipe was opened and the lungs inflated, but these and other means failed to initiate spontaneous breathing, and the patient died. There are many most unsatisfactory points about this case which perhaps a fuller report than that which has reached us might clear up. We are not told why tracheotomy was performed, although presumably for obstruction. Such obstruction could hardly have been spasm, as it occurred *twelve* minutes after commencing the ether, and subsequently to complete narcosis. If it was due to vomiting, it should have been mentioned, and surely a post-mortem examination should have been made to ascertain whether the vomit was sucked into the air-passages. Such an event constitutes the main danger in these cases, and several instances have occurred comparatively recently in metropolitan hospitals in which, through no fault of the administrator of the anæsthetic, vomit has found its way into the lungs. It seems most extraordinary, unless some such gross impediment to respiration occurred, that, with a heart beating for ninety minutes, respiration could not be restored. Was this efficient? Was there emphysema or any other condition which rendered artificial aeration of the blood impossible? If not, it seems very unusual that twelve minutes of etherisation carefully performed, as we are told it was, could not be counteracted by ninety minutes of artificial respiration.

A death under chloroform is reported from Wolverhampton. The patient, a boy aged eleven, suffering from hip-joint disease, was admitted into the General Hospital for operation. He had taken chloroform successfully twice (in September and October) during last year, and was again placed under its influence by the house physician for a third operation. When the surgical procedure was completed the boy's face grew dusky and his pulse stopped. The house surgeon's report after a necropsy was that death arose from syncope. The facts before us are too scanty to justify any remarks upon the case except to call attention to the fact, now pretty generally recognised, that there is no immunity from subsequent danger enjoyed by those who have passed safely through chloroform administration once or twice on previous occasions.

THE ROYAL BRITISH NURSES' ASSOCIATION.

THE meeting of this Association which was held on Monday last had under consideration a proposal to substitute a Royal Charter for the statutory incorporation under the Companies Act to which the application to the Board of Trade recently made for a licence to register a title without the word "Limited" was a preliminary. By a unanimous resolution the meeting decided to adopt this course, and thus the history of the institution enters upon a new phase. We do not doubt that the committee which has recommended the new departure has carefully considered the alternatives and been well advised as to the choice to be made. But we should, for our part, have been well content to hear that the Society had determined to press its claim upon the Board of Trade, for a position more thoroughly indefensible was never taken up by a public officer than that assumed by Sir Michael Hicks-Beach when he refused the application for a licence upon grounds of such a general character as those alleged in his communication to the Society. His treatment of the Institute of Preventive Medicine was at first equally perverse, but the firm attitude of the promoters induced him in the end to give way. It would, however, be very unreasonable to complain of the Association that it had declined a troublesome and disputatious course if an easier and simpler one be open to it. At the Privy Council Office there will be at least no mistake as to jurisdiction, and no attempt to adjudicate upon the merits of the application without hearing its promoters. In these circumstances the meeting had good ground for the tone of confidence which marked its proceedings, and it would not be surprising if in the end it should prove that the perversity of the Board of Trade turns to the advantage of the Association. In one respect it has done so already, for the Princess Christian has been induced to signify her approval of the institution in a very emphatic way, and to renew a very effective support by announcing that she will head the application to the Privy Council with her own name. While the battle remains to be fought it would as yet be premature to con-

Digitized by Google

gratulate the promoters of the British Royal Nurses' Association; but we certainly shall not condole with them upon events which, though apparently untoward, have so far had such excellent results.

INFLUENZA.

THERE is comparatively little to report concerning the epidemics of influenza, either in this country or abroad, for, indeed, in almost all parts it seems to be subsiding. Thus in London—where, it may be noted, the birth-rate has regained its usual supremacy over the death-rate—the deaths directly attributed to influenza amounted last week to 314, as compared with 436 in the preceding week, and the cases in which influenza was noted as a secondary cause fell from 71 to 62. It is gratifying also to record a notable decline in deaths from respiratory diseases—namely, from 1465 and 1192 in the preceding two weeks to 761, a figure which, however, exceeds the corrected average by 279. The total death-rate in the metropolis last week was 30·6 per 1000, the same as at Portsmouth, and exceeded amongst the large towns of England and Wales only by Norwich (39·6) and Preston (31·1). Indeed, the general average amongst the thirty-three great towns noted in the Registrar-General's weekly return was 26·2. The chief fact to record in connexion with influenza has been the appearance in Vienna of an outbreak of diarrhœa, which has been extremely prevalent in that city during the past fortnight. It was at first supposed to be connected with the drinking water; but several of the leading physicians discountenance this theory, which has little to support it, and their general impression favoured its association with the prevailing epidemic. Dr. Bettelheim stated that as soon as this intestinal catarrh assumed an epidemic form, cases of the ordinary type of influenza ceased to appear. It is indeed quite conceivable that the two are related, and that in this enteritis we have only another example of one of the multifarious ways in which the influenza virus acts upon the organism.

ENTERIC FEVER AT THE FOUNDLING HOSPITAL.

AN exhaustive report has been prepared by Dr. John F. Sykes on an outbreak of enteric fever at the Foundling Hospital. The first case was admitted to the infirmary on Oct. 8th of last year, and between that date and Dec. 14th there were thirty-five attacks, with, happily, only one death. At first sight there were certain indications afforded by the special incidence of the disease which seemed likely to become helpful in ascertaining the origin of the malady. Thus, in the east wing, containing 179 inmates, only three, or 1·7 per cent., were attacked; whereas in the west wing, with 185 inmates, no less than thirty-two, or 17·8 per cent., suffered. Then, again, thirty-three of the patients were girls or female officers, only two males—both boys—being attacked. But the inquiry turned out to be very difficult. A continuous operation of the infection seemed indicated by the rapidity with which new attacks occurred within a few days of each other right up to the end of the first week of November; but, notwithstanding a most painstaking inquiry, nothing definite could be made out as to its primary introduction into the buildings, or its origin within them. The cause of the maintained diffusion is referred by Dr. Sykes to a faulty arrangement as to drainage by which the contents of the infirmary drains were made to flow past a grease-trap connected with the cooking room; these drains containing, for fully a week, infected stools from enteric fever patients. This grease-trap is regarded as having formed a suitable incubation chamber; and it is believed that the arrangements connected with it must have secured a rush of warm, expanded air and vapour into the kitchen, the offices, and the neighbouring staircases. When the kitchen was closed at night, and after evening meals, those most engaged in the kitchen—namely, the female staff and some elder girls—would be most subjected to the mischief, whereas the school children would have gone to their school-rooms at a distance. The special incidence of enteric fever on age would also necessarily have had some influence on the attacks amongst the older of the female inmates. The boys would not come under the influence of this defective arrangement in anything like the same way, and to this their immunity is attributed. The method of inquiry adopted by Dr. Sykes is worthy of study and imitation, even though in some respects his labours were not rewarded by a full discovery of all the circumstances which he endeavoured to clear up.

THE USE OF THE ACTUAL CAUTERY IN GYNÆCOLOGY.

DR. V. STOLYPINSKI, in an article in a Russian medical journal, strongly recommends the more frequent use of the actual cautery in gynæcological operations, as, for instance, in the destruction of fungating cancer, for the arrest of bleeding from pedicles, and for the removal of small tumours. He uses it in the removal of the vaginal portion of the os, when required, for malignant disease, and recommends it on account of its easy application, the slight loss of blood, and the simple after-treatment. He reports only one case with an unsatisfactory result, obliteration of the os being found at a subsequent confinement.

DEATH BY HANGING.

THE *St. Petersburger Medicinische Wochenschrift* gives a *résumé* of a paper by A. S. Ignatovski on the cause of death by hanging. He refers the rapid loss of consciousness after suspension to the retarded or arrested circulation in the brain brought about by the increased intra-cranial blood pressure. The effect of this impediment to the circulation is the same as in cerebral anæmia, for in both the nutrition of the brain suffers. It is therefore not, as Leofman teaches, an insufficient supply of blood to the brain, due to compression of the carotids, which interferes with the functional activity of the brain, but compression of the capillaries by increase of the intra-cranial pressure, which has this effect, and which occurs whilst the supply of blood remains the same, or even increases.

SIR SPENCER WELLS IN INDIA.

WE learn from the *Englishman* of Calcutta that Sir Spencer Wells has been the guest of the Medical Society of Calcutta, at a crowded meeting presided over by Dr. Kenneth Macleod. The assembly included most of the leading practitioners in Calcutta, European and native, a number of lady doctors, and some of the more advanced students of the medical college. We can imagine how sincere were the words in which Sir Spencer Wells expressed his pleasure in seeing such an assembly, representing so many different races and creeds, and receiving from it a warm welcome—the more so as the great subject of the evening was entirely congruous. The proceedings were begun by a paper on Ovariotomy in Calcutta by Dr. Joubert. Sir Spencer Wells paid a just tribute to the success of surgery in India, especially to the treatment of elephantiasis by the President, of lithotomy and lithotrity, of cataract and of hernia. Not less to the point was the praise awarded to the profession in India for its less showy but equally important work of an administrative and sanitary kind, fraught with blessing as it is to nearly three hundred millions of our fellow-subjects. Of course, Sir Spencer Wells did not conclude his eloquent address without a reference to ovariotomy in India, which had been so well represented in practice and on paper by Dr. Joubert. He thought the

Digitized by Google

success had followed the European success, slowly at first, but gradually coming up to it. Sir Spencer Wells was liberal in his recognition of the other great advances in abdominal surgery, though he claimed that these were largely based on the success of ovariotomy. Not the least interesting part of his address was his allusion to the large number of deaths in Calcutta (12,000 in ten years) from tetanus, especially among infants. According to Dr. Simpson, 500 infants died of tetanus in Calcutta in 1890. Whether microbic or not in its origin, this is certainly a mark of insanitation. It reminds us of the appalling mortality of infants in the Rotunda Lying-in Hospital, a hundred years ago, from trismus nascentium, which was entirely removed by the simple expedient of opening the windows. Sir Spencer Wells supported the proposal to cremate the town refuse as one of the most likely ways of abating this virulent disease. We trust his example will be followed by other men of light and leading, who may be confident of a cordial reception in Her Majesty's Indian territories.

THE INTERNATIONAL MEDICAL CONGRESS OF 1893.

THE profession in Italy is sparing no pains to make this meeting as conspicuous a success as the best of its predecessors. At a recent sitting in Rome an organising committee was formed, with Dr. Baccelli as its president; Professor Edoardo Maragliano of Genoa, general secretary; the Commendatore Professor Pagliani (head of the Public Health Department of Italy), treasurer; and the Commendatore Signor Ferrando, steward (*economo*). There were also elected by ballot the heads of the fourteen sections over which the work of the Congress is to be distributed—to wit, Anatomy, Physiology, Clinical Medicine, Gynæcology and Obstetrics, General Pathology and Pathological Anatomy, Pharmacology, Surgery and Orthopædics, Psychiatry and Neuropathology, Ophthalmology, Dermosyphilopathy, Legal Medicine, Hygiene, Laryngology and Otology, Naval and Military Sanitation. The committee is at this moment engaged in constituting local or subcommittees for the whole kingdom, to consist of the leading practitioners of every province. All this procedure is on the lines of the Berlin committee, which will also be imitated in giving to each provincial representative a distinctive badge, to be worn during the Congress. The committee, moreover, is proceeding to the election of foreign committees with a view to secure the presence at the Congress of the leading members of the profession in all parts of the world, so as to make the gathering as truly an international one as possible, worthy of its predecessors and worthy of Rome. The time of meeting has been fixed for September, the month in which the climate of central Italy is at its best, when in Rome there is no risk whatever from malaria, and when the profession, particularly of North-western Europe, can best be spared from home.

KNEE-JERK IN ACUTE ILLNESS.

IN the last number of the *Neurologisches Centralblatt* there is an abstract of a paper by Dr. Longard of Bonn which deals with the condition of the knee-jerk during feverish conditions and with the influence of psychical conditions upon the phenomenon. In eighty-two patients suffering from phthisis he found distinct foot clonus in no less than thirty, and in seven of those there were active periosteal and other reflexes. Of those seven, six had a high temperature and were much emaciated, and only one was free from fever and fairly strong. In the majority of those there was active idio-muscular contraction in the pectoralis major and biceps, and in only a small number was it absent. The activity of this phenomenon seemed to be proportional to the amount of feverishness. In four cases of typhoid fever the knee-jerks were distinctly increased during the illness or in convalescence, and in one case of acute rheumatism there was a slightly increased activity of the knee-jerk. Of eight cases of croupous pneumonia, in seven there was increased knee-jerk and an increased muscular irritability, but there were among them three cases in which, at the height of the illness, the knee-jerk could not be elicited. Dr. Longard believes that in such acute illness the products of the morbid process may increase the irritability of nervous structures without causing any discoverable structural alteration in them, and he also believes that psychical influences are more effective in modifying the reflexes than has hitherto been supposed. Rosenbach finds diminution of the reflexes during sleep, and that this diminution is proportional to the depth of sleep; and in some of the cases observed by himself Dr. Longard was able to demonstrate a variation in the activity of the reflexes according to the psychical state of the patient. He concludes that the presence of foot clonus, or even of patellar clonus, is not necessarily dependent upon degeneration of the pyramidal tracts.

SMALL-POX IN THE DEWSBURY UNION.

THE Local Government Board have now issued an order definitely prohibiting the admission of small-pox cases into the Dewsbury workhouse hospital, and it is curious to note that this is protested against by one of the guardians on the ground of sympathy with the "needy class who want shelter." If the guardians who want to import small-pox cases from Batley into the workhouse at Dewsbury, where they are kept within a few feet of the needy sick in the infirmary, and where the lives of these sick poor have again and again been endangered, would use their influence in precisely the opposite direction, then their anxiety for the needy class would be more intelligible. The West Riding Council have also seen the matter in the same light as the Local Government Board, and have informed the guardians that, under the circumstances, they will refuse to receive any more pauper lunatics from Dewsbury. This is also objected to by the guardians, who have instructed a committee to wait upon the Asylums Committee of the County Council. In the meantime, we are glad to find that a number of urban authorities within the area of the Dewsbury Union are uniting for the formation of a joint infectious hospital board, the public inquiry for this purpose having been held last week. Some such means of proper isolation has long been wanted, and it is to be hoped that speedy success will follow this initiative step.

RECENT DEVELOPMENT OF ELECTRICAL SCIENCE.

LAST week, at the Royal Institution, Mr. Nikola Tesla, a native of Dalmatia, now settled in America, demonstrated the recent and most remarkable practical results of his investigations in electrical science. These have proved to be the most important advances of recent years; indeed, they may be regarded as a novel departure from the ordinary methods. The great novelty consists in the employment of alternating currents of high potential and frequency, the alternations taking place as rapidly as 20,000 times per second, which may be increased to a million per second by passing the disruptive discharge from a battery of Leyden jars through the primary current of an induction coil. When such a current is passed through a bare metallic wire it glows in the dark, and if one pole merely be attached to a metallic point a bluish flame becomes visible, or if to small discs of various substances, as lime, carbon, or artificial diamond in vacuum tubes, these become brightly incandescent. The incandescence increases to a bright light when

Digitized by Google

the hand is brought close to the bulb, and still higher brilliancy is attained by the use of an ordinary metallic shade. A remarkable series of experiments shown by Mr. Tesla was the glowing of vacuum tubes without attachment by any conductors when these were simply held in a space between the two poles, the one terminal being a sheet of metal overhead. This showed the possibility of rendering any space electric (say, a room), and of the employment of vacuum tubes, placed anywhere in this electrified area without connecting wires, to yield light. One of the most important features, from a medical point of view, is that these rapidly alternating currents of extremely high potential appear to be absolutely without any pernicious effect on the human body, for Mr. Tesla made his body a portion of the circuit, and took a vacuum-tube (which glowed brightly) in one hand and an iron rod in the other, with which he touched one of the terminals from which sparks of several inches were being emitted, and yet seemed perfectly unaffected, whereas ordinary currents of probably one-fifth the intensity would cause death instantaneously. The condition of minimal displacement, while it has enabled Mr. Tesla to penetrate into what has been not inaptly described as a new region of experiment, shuts him out from the use of many of the appliances with which in the ordinary uses of electricity we are familiar, and therefore, although the beauty and interest of his experiments may be freely acknowledged, their practical utility or even their promise of practical result has yet to be demonstrated. The exhausted tube is a beautiful and, even under favourable conditions of illumination or rather of darkening, a brilliant object to look at, but it is a very feeble source of light; and there does not seem to have been in Mr. Tesla's experiments any indication whatever of such an increase of efficiency in his use of electricity as points to the use for practical illuminating purposes of such currents as he is able to pass through the human body without inconvenience.

THE LATE DR. H. I. BOWDITCH.

By the death of Dr. Bowditch on Jan. 14th, at the advanced age of eighty-four, there passed away one who in his time rendered great service to medicine, and whose memory will be long cherished at Boston and at Harvard University, where he was once the professor of clinical medicine. The *Boston Medical and Surgical Journal* (Jan. 21st) gives an admirable account of his life, taking note not only of his educational and professional careers, but of his energetic support of the movement for the abolition of the slave trade, in connexion with which may be cited the following fact: "When he was appointed admitting physician [to the Massachusetts General Hospital in 1838], negroes were not received as patients in the hospital. He offered a test case of pneumonia, resigned his position when his negro patient was not admitted, and carried his point, his resignation not being accepted." As may be gathered from this incident, Dr. Bowditch was a man of a chivalrous type and boundless sympathy. "Honest, fearless, outspoken, he made friends of his enemies by the simplicity, purity, and unselfishness of his purpose. He compelled an admiration of the right and a hatred of wrong." As regards his professional work, it may be noted that after graduating he spent two years in Europe, studying chiefly under Andral, Chomel, and Louis. His best-known work is his advocacy of paracentesis thoracis, in which he employed the aspirator invented by Dr. Wyman. This was in 1850, and may be said to have been the starting-point of a measure which subsequently became generally adopted, although not without encountering much opposition. Another subject which much interested him was that of phthisis, and in particular its association with climatic conditions, in which he did for America work similar to that carried on by Dr. G. Buchanan in his memorable inquiry on the prevalence of consumption in this country. He produced many essays on these and a few other subjects, but he published no large work. It is said that he has left "more than 90,000 manuscript papers of records of cases of private patients." He was one of the first supporters of female medical education; he was also mainly instrumental in the creation of the first State Board of Health in the United States in 1869, and acted as president of that board till 1879. He fully earned and merited the esteem and affection with which he was regarded.

HEALTH OF IRELAND.

UNDER this heading Dr. C. F. Moore of Dublin has recently published an article bearing on the health of Ireland, and more especially the sanitary condition of Dublin. He points out by statistics calculated on the last twenty years, taken from the death-rate, of almost every country in Europe, that Ireland ranks, after Norway and Sweden, as the most healthy of the European countries; and if the regulations for the sale of fermented drinks which prevail in Norway and Sweden were adopted in Ireland, he believes the latter country would far excel the other two named in healthfulness. Dr. Moore next refers to the plans for Dublin main drainage, but thinks a good deal might be done to improve Dublin without recourse to increased taxation in experimental, chemical, and engineering works. He draws attention to the accumulation of manure heaps in various parts of the city, and to the number of slaughter yards which the corporation cannot close without giving compensation to their owners, and points out that knackers' yards, tanneries, and other offensive works should be carried on outside Dublin, and all resulting offensiveness should be prevented flowing into the sewers. At a meeting of the Dublin Corporation last Monday Alderman Perry stated that he had personally inspected numerous tenement houses and dairy houses in the city, and that the condition of the former were in many instances most unsanitary. He attacked the Public Health department, which was defended by several members, and ultimately the matter was referred to a committee to inquire into the working, and make such recommendations for the reorganisation, if necessary, of the department as may appear to be necessary, Alderman Perry undertaking to formulate in writing specific statements of default in connection with the present working.

SEED GROWTH AND ELECTRIC CURRENTS.

SOME experiments, very simple, but of quite startling interest, are described in last week's number of the *Chemical News* (Feb. 5th). Dr. James Leicester, of the Merchant Venturers' Technical School, Bristol, has been studying the growth of seeds in what may be described as electrified earth. Scarcely any apparatus was used. A box about three feet long and two feet and a half wide was filled with soil, and near each end two metal plates, one of zinc, the other of copper, each about one square foot in size, were immersed, and were united outside by a copper wire. It is evident that by slow chemical action on the zinc a current will pass through the earth towards the copper, and returning by the outside copper wire will form about the simplest of simple cells. Various seeds were sown in the earth between the plates, and in every case it was found that the seeds grew much quicker than they did when the plates were absent. Similar and even more definite experiments were made with glass tanks, some with and some without the metal plates. All of them were fitted with the same earth, and were treated with the same quantities of water. In one typical instance

Digitized by Google

the result is thus stated: "In the case of hemp seed, it was fully an inch above the surface before there was any sign of it in the ordinary vessels." The experiments were varied in several ways, but always with substantially identical results. It was found that if the soil was watered with a little very dilute acetic acid the growth of the seeds was much quicker when the metal plates were present, whereas without them no difference was noticed. Further researches on the growth of plant life are in progress, but have as yet yielded only negative results. It is impossible to anticipate the importance which may in future attach to these remarkable observations. They have no analogy at all with the experiments of Dr. Siemens, also interesting and important, on the stimulation of vegetable growth by electric light. Everyone knows that electric light is closely analogous to solar radiation, and it is not wonderful that the work of the sun's rays can be imitated, if not equalled, by their only important rival, the voltaic arc. But in these experiments there is no question of light or heat radiation, but a subterraneous impulse imparted to the soil.

CHOLERA INTELLIGENCE.

IT is for the first time definitely stated that all cholera in and around Damascus has disappeared; and it had for some time previously ceased at Beyrout. But in the plain of Merj-Ouni, some seventy miles from the latter town, cases are still said to be by no means unfrequent, and the consequence is that Syria and Asia Minor remain under observation as regards the prevalence of this disease.

INDIAN MEDICAL SERVICE.

AS our readers are aware, the question arose some time ago as to whether Brigade Surgeons of the Indian Medical Service could decline promotion to the rank of Deputy-Surgeon-General. Medical officers holding lucrative civil appointments were naturally disinclined to relinquish them, and occasionally preferred to abandon their claim to the higher rank rather than do so. We learn from the Indian press that it has now been ruled that if, after considering all the circumstances affecting any particular case, the Government deem it expedient in the interests of the public service to nominate a Brigade Surgeon for promotion, that officer will not be given the option of refusing it. We said, when the question arose some time ago, that the Government was clearly within its rights in this matter, and that all that could be fairly expected of the Government was that each case should be considered on its merits, and decided in the interests of the public service.

SLEEP AND MORBID SOMNOLENCE.

THE case of Johann Latus, the miner of Breslau, who was recently reported to have lain asleep for a continuous period of four months and a half, though not unique, affords a remarkable example of morbid somnolence. Though we cannot yet speak precisely as to the physiological basis of sleep, we can still gather from observation of associated physical states, aided by the side-light reflected from their pathological counterparts, some idea of its essential meaning. The fact that the brain becomes anæmic during sleep, though probably as much a consequence as a cause of this condition, is instructive nevertheless, as indicating that the molecular tissue changes underlying it are those of rest, the sequel of exhaustion; and further, that they are not merely cerebral, but are shared by every organ. It is manifest, at the same time, that the normal state of periodic sleep must be aided and deepened by this reduction in the ordinary nutrition of the brain. When, again, we come to deal with the causes of morbid drowsiness, the properties and relation of the nutrient blood-supply acquire a fresh interest. It would be impossible, unless we took account of these, to judge of the influence exercised by such well-known causes of unnatural stupor as the various forms of toxæmia, or even perhaps of the similar phenomena connected with obesity, myxœdema, senility, and nervous prostration. In most of these conditions the nerve exhaustion is remediable, and that by means which operate either on or through the circulatory system. Among such are massage and electricity, which act by stimulating its movement if too sluggish, and thus promote waste excretion, while at the same time they aid the direct nutrition of the jaded nerve centres. We may take it, therefore, that the somnolent condition, whether in health or illness, is a natural, and in some degree a remedial, consequence of nervous exhaustion. It may be of transient or of more continuous duration.

HÆMATOMA AURIS IN THE INSANE.

DR. TISHKOFF has examined and reported upon ten cases of hæmatoma auris occurring in patients suffering from general paralysis of the insane, in which disease it differs both clinically and pathologically from other forms of hæmatoma attacking the ear. Hæmatoma auris is due to the exposure of the cartilage of the ear to external influences, rendering it susceptible to morbid changes. It commences with inflammation of the perichondrium, which is followed by absorption of the cartilage caused by the formation of new bloodvessels. The rupture of these vessels creates a cavity between the perichondrium and the cartilage, which increases as the flow of blood continues. The characteristic form of the hæmatoma is caused by the cavity between the cartilage and perichondrium. The blood is slowly absorbed, and the thickness of the walls of the cavity is augmented by a new growth of connective tissue. The exciting cause in the insane is generally maniacal excitement; in the healthy it is always traumatic.

A CHEAP METHOD OF ADMINISTERING FAT.

DR. MERSHINSKI, by boiling milk and lard together for a considerable time, prepares a liquid which contains a large percentage of fat, one litre (one pint and three-quarters) containing from 130 grammes to 170 grammes. He gives half a litre before rising and another at eleven o'clock. "Breakfast," at one o'clock, consists of carbohydrates; dinner, at five, of nitrogenous matter. Experiments prove that the diet is generally well digested, and that the patient increases in weight. Dr. Mershinski considers this preparation very suitable for hospital and union practice in cases of malnutrition not connected with disease of the stomach, liver, intestines, or pancreas.

NEWSPAPER CURES FOR INFLUENZA.

ONE of our religious contemporaries, with doubtful judgment, leaves the region of divinity and professes to give its readers the wisdom of the late Sir Oscar Clayton in reference to the treatment of influenza. It is very curious reading, and somewhat hard on the deceased knight bachelor, whose prescription is given in very lax form, and who probably did not contemplate its general application. A certain "mixture" (*sic*) is to be taken with a tablespoonful of lime juice. We pity the unfortunate reader who takes the instructions too literally. Our contemporary then continues: "If I were you," added Sir Oscar Clayton, "I would eat two oranges a day. They are an excellent thing for influenza. They keep it from the chest." Was there ever a more simple and withal more pleasant protection from so grave a complication as that from bronchitis, pneumonia, and pleurisy by the palatable expedient of taking two oranges a day! Not only so, but it

Digitized by Google

is set off with equally palatable accompaniments. "You may have a little fish or chicken, and have two glasses of port wine a day made into negus. Add a bit of lemon or nutmeg. Take plenty of strengthening food," &c. Who can resist such prescriptions, especially when they are said to proceed from "An eminent Court Physician"! Our contemporary naïvely adds that it is a curious coincidence that Sir Oscar Clayton should have died of mere influenza. The suggestion is that people die of the dreaded chest complications. But then there are the two oranges a day to keep these off. It is rather cruel to deal so lightly with the prescriptions of a deceased practitioner. It is hard enough for a medical man to be responsible for prescribing for individual patients without having given to his prescriptions a universal application. Our contemporary must take on itself the great responsibility of any extension in the demand for port wine that may accrue from this paragraph. People are extremely ready to take port wine, especially with the double sanction of a religious newspaper and "an eminent Court physician."

THE LIVERPOOL SOUTHERN HOSPITAL.

AT the meeting of the trustees and subscribers to this hospital it was described by several of the speakers as "a fitting monument of the generosity of the people of this city." The sanitary system has been overhauled at a cost of £2000, and a theatre has been built for the performance of surgical operations. Mr. Wm. Adamson, in seconding the report, referred to the growing recognition of the advantages of the hospital as a clinical school and as an institution for instruction in practical medicine and surgery, and to the fact that the Southern Hospital had been fully recognised by the Royal Colleges of London as a complete school of clinical medicine and surgery, standing in exactly the same relation to University College as the Royal Infirmary of Liverpool.

VARIATIONS IN THE SIZE OF THE PELVIS DUE TO ITS OBLIQUITY.

J. J. FEDOROFF publishes in a Russian gynæcological journal an article on the variations in size of the pelvis of parturient women due to its degree of obliquity. Last year, after careful observation of eight cases, he came to the conclusion that the conjugate diameter varies in length, and that its increase is due to the amount of pelvic inclination. He also found that the adaptability of the child's head to the pelvic brim, in flat and narrow pelves, is considerably increased in Walcher's position—that is, when the child's breech lies higher than usual and the lower extremities are extended. Measurements on thirty-six patients have led him to confirm his previous statements, and also to extend to them the other diameters of the pelvic brim, as in like manner depending on the obliquity and narrowness of the pelvis.

DEATH CERTIFICATION OF INSURED CHILDREN

WE are pleased to notice that the authorities are disposed to supervise with due vigilance the certification of deaths occurring among insured children. Let us take a recent example. At Cheltenham, on Jan. 26th, Mr. M. F. Carter, the acting coroner, held an inquest on the body of an infant who had died suddenly. The child had been ill for a week, but until the evening of his death had received no medical attendance. He was then seen by a medical man and prescribed for, just in time to allow of the latter signing the usual certificate. In this instance, notwithstanding the obvious neglect in delaying so long to summon assistance, there was no suggestion of evil intention on the part of the parents, and a verdict was given in the terms of the certificate, assigning congestion of the lungs as the cause of death. Notwithstanding this result, there can be no question as to the expediency of an inquest in this case. Others of a like sort, but by no means above the suspicion of criminal practice, have been marked by identical characters—the fact of insurance, the same neglectful delay, the same rapidly fatal issue. If we would add anything to the remarks already made it would only be to emphasise the duty incumbent upon medical practitioners to use the greatest circumspection in dealing with such cases. We have nothing to say against the practitioner's judgment in granting the certificate already referred to, but we should, in the absence of specially palliative considerations, regard such parental neglect as here occurred as in itself deserving of exemplary exposure.

THE EDINBURGH UNIVERSITY CLUB.

THE club was at its best on Wednesday night, under the genial presidency of H. Rutherfurd, Esq., barrister-at-law, who showed that while the medical faculty of the University had predominated for 150 years, men of other faculties gave lustre to the University. There was a goodly attendance. Previous to the dinner the annual meeting was held, and the reports were, on the whole, satisfactory. The chief event of the evening, regretted by all, was the retirement of Dr. Pringle from the treasurership, which he had held so ably for five years. His health was very feelingly proposed at the dinner by Dr. Potter.

FOREIGN UNIVERSITY INTELLIGENCE.

Naples.—This university, which was closed because of disturbance amongst the law students, has now been re-opened.

St. Petersburg (Military Medical Academy).—The lectures on Special Pathology and Therapeutics and the clinic formerly under the charge of Professor Manassein have been entrusted, during the vacancy caused by that gentleman's resignation, to Professor Chudnovski.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.

THE deaths of the following distinguished members of the medical profession abroad have been announced:—Dr. Alexander Lumnitzer, formerly Professor of Surgery in the University of Buda Pesth, at the age of seventy-one, after many years' ill-health.—Dr. Ed. Coen, lecturer on Pathological Anatomy in Bologna.

THE second of the Hunterian Society's Lectures for 1891–92 will be delivered by Dr. Hughlings Jackson, F.R.S., in the large lecture theatre of the London Institution, Finsbury-circus, on Wednesday, Feb. 24th, at 8.30 P.M. The subject of Dr. Hughling Jackson's lecture will be "Neurological Fragments," and the lecture is open to all members of the profession.

THE 119th anniversary dinner of the Medical Society of London will take place at the Whitehall Rooms, Hôtel Métropole, on Saturday, March 12th, R. Douglas Powell, M.D., F.R.C.P., President, in the chair.

MR. W. W. E. FLETCHER, M.B. Cantab., M.R.C.S. Eng., &c., medical officer of health of the Ormskirk Union, has been appointed to one of the medical inspectorships under the Local Government Board.

MR. W. HEATON HAMER, B.Sc. Lond., M.D. Cantab., M.R.C.P. Lond., has been appointed Assistant Medical Officer of Health of the London County Council, at a salary of £500, rising to £600.

Digitized by Google

MEETING OF THE GENERAL COUNCIL OF THE UNIVERSITY OF EDINBURGH.

ON Friday of last week (Feb. 5th) a special meeting of the General Council of the Edinburgh University was held; it was convened by the Chancellor, the Right Honourable A. J. Balfour, in virtue of a requisition presented to him by a quorum of members of Council. Sir William Muir presided, and there was an unusually large attendance of members. The reason of this special meeting was that since the last statutory meeting of Council in the end of October, 1891, two draft ordinances issued by the Universities Commissioners had been received by the Secretary of the Council—viz., General No. 9, Regulations for Graduation of Women, and General No. 10, Regulations as to Assistants and Lecturers. Both were issued in the middle of November, and any amendments or objections had to be submitted to the Commissioners on or before the 16th of the present month. The draft ordinances referred to were considered by the Standing Committee of Council on communications to the Commissioners, and who prepared reports thereon, which were submitted to the meeting on Friday. The report on Draft Ordinance, General No. 9, points out that this ordinance enables the University Court of each University to admit women to graduation in arts and medicine, and makes such provision for their teaching as in the opinion of the committee would tend to place the University education of women in these faculties on a basis of substantial equality with men as far as the necessarily permissive character of the ordinance admits. Exception is taken to there being no opportunity left open for considering any similar provision in future in law or divinity. The committee regard the provisional clauses, recognising extra-academical teaching as qualifying for graduation so long as University classes are not fully available for women, to be fair and reasonable; but they urge that these clauses should be so far retrospective as to enable the courts to take account of students who have already attended regular courses and obtained certificates in examinations of the same character and standard as those for the M.A. degree. This report as well as the following were submitted by Mr. Taylor Innes, advocate, convener of the committee.

The second report was on the ordinance dealing with assistants and lecturers. The committee point out that from want of definiteness they have had difficulty in judging readily of this ordinance, more especially as to the means of increasing the teaching power in the University. The increase is necessary from the admitted evil of excessively large classes, the desirability of dividing large and important subjects into several departments, and the urgent necessity of increasing the number of, and the attendance at, practical classes in the Medical Faculty. In dealing with a former draft ordinance the committee expressed approval of two modes of diminishing the evil of excessively large classes (1) by enlarging the duties and improving the status and emoluments of University assistants; and (2) drawing more completely into the University system the extra-mural teachers in Edinburgh. In addition, there is a third expedient which the committee desire to see adopted—namely, subdividing Chairs, and appointing additional professors. The report then proceeds to deal with the proposals of the ordinance as regards (1) assistants and (2) lecturers. As regards assistants, the committee points out that the provision that they are to be paid out of the University funds will throw an additional burden on these, and will at the same time relieve those professors who at present pay a share, if not the whole, of their salaries. The committee see no reason why professors who draw a large amount of fees from practical classes should be relieved of the burden of paying those who do most of the work, especially as the effect of the present arrangement is to enable the professors to engage either in private research or in private professional practice. The committee further suggests that the duties of assistants shall be approved by the University Court as well as by the Senatus, seeing the duties are defined by the professor. The senior assistants in the Medical Faculty not only deliver lectures in supplement of those of the professors, but, in their absence, deliver lectures in the ordinary courses, and that in addition to conducting practical classes, superintending the laboratories, and reading examination papers and essays; and this being the case, if the Commissioners intend to make a change in their duties by the use of the term "tutoral work," it ought to be clearly defined. They further suggest that the chief assistants should have a distinctive title. The assistants are appointed on the recommendation of the professor. As regards lecturers, the ordinance provides for two classes: (1) the subjects not already taught in the University; and (2) on subjects already taught in part, with a view to preparing candidates for graduation in honours and in subjects not fully covered by the professor's lectures, and also with a view to increasing the teaching power when that is desirable. The ordinance determines that assistants shall be eligible as lecturers and *vice versâ*, and the committee take serious objection to this, and strongly recommend that the same person should not be allowed to hold office in both capacities. The committee further comment on there being no provision for initiating proceedings for the establishment of lectureships. They further regret that ambiguities appear which suggest a doubt whether the lecturers are intended to be really independent and not merely assistants under another name. They also contend that powers over teaching and teachers should be retained and exercised by the University Court. They think, further, that the Court should have power to make appointments of independent lecturers on subjects already taught within the University, not merely when it appears to be necessary, but when it appears to the Court to be desirable. The foregoing gives but an outline of the report, but sufficient to indicate its scope and the main points insisted on.

Dr. HAYCRAFT moved that the following be an addition to the committee's report:—

"The Council regrets that the University Commissioners do not propose the creation of any new chair in the Faculty of Medicine, and submit that if the Commissioners are not prepared to take the initiative in this matter, the staff of the University would remain, in their opinion, inadequate both for teaching purposes and for the direction of original research; that an addition of thoroughly capable and experienced teachers is necessary, as no addition to the medical professoriate has been made since 1836, in spite of the enormous increase of students, the institution of many new classes, and the development of a number of recognised specialities not known at that time. There is ample room in every department of the Faculty for the creation of at least one fresh speciality, and even then the specialisation would not be as great as that in an average German University. It is not to be expected that this addition to the teaching staff will be made by means of assistant lecturers proposed by the Commissioners. In order to obtain and retain the services of capable and experienced men, a University status, independent of the jurisdiction of another endowed lecturer, and emoluments of at least £400 a year ought to be provided."

Dr. Haycraft supported his motion in an admirable speech. Referring to the statistics of forty foreign Universities, he found that at these there was an average of twenty-five or twenty-six professors in the medical faculty; at Berlin and Vienna the number was over sixty. That was evidence of specialisation beyond anything they had in Scotland; and even in the extra-mural school in Edinburgh there was a specialisation going on which was distinctly in advance of the University. Considering the degree of specialisation developed abroad, and the fact that a considerable amount of time was spent by a number of the professoriate of Edinburgh in duties outside their University work, he submitted that, as a result, no great original work could be turned out at the University under present circumstances. He then referred to the inadequate remuneration of the assistants who were doing professorial work, and the fact that the new regulations did not improve their position. He did not think that any man of capacity and experience would ever retain his post with a one-year appointment and an insufficient remuneration, and that entirely under the jurisdiction of any individual member of the faculty. There was no attempt on the part of the Commissioners, and from the knowledge they possessed he did not think there would be any attempt on the part of the medical faculty in the University, to increase the number of men who would be able to remain at the University to take up differential work and add to its prestige. A young teacher might be got to accept the position, but he would take the first appointment elsewhere, and the University would only retain the services of young men or men who had failed to get positions elsewhere.

Dr. BERRY HART seconded this motion, and dwelt on the fact that, although Lister had done much of his great work in Edinburgh, bacteriology, upon which his work was based, had gone to France and Germany.

Mr. TAYLOR INNES accepted the proposed addition to the report, which was accepted without opposition.

Digitized by Google

Dr. CATHCART then moved: "That the General Council of the University of Edinburgh deem it advisable that in any scheme of medical reform provision should be made by the University Commissioners for insuring the diminution of the number of systematic lectures, increasing the practical work, and allotting at least two years for the final subjects, and that careful provision be made for more thorough and efficient examination in all the professional subjects."

This was seconded by Mr. CAIRD and agreed to unanimously. This motion originally contained a clause in favour of the establishment of an honours school; but as this clause was to be opposed, it was made a separate motion

Dr. BYROM BRAMWELL, supported by Dr. NOEL PATON, opposed this motion, the former taking the same line of reasoning followed by him at the public meeting of the Reform Association.

On the suggestion of Mr. TAYLOR INNES a compromise was arrived at in the following terms: "That provision be made for honours being awarded in respect of high distinction in special departments of medicine, as well as in respect of high general excellence."

In the discussion on the Honours School, Professor RUTHERFORD enlarged upon the excellence of the University and its present methods, and was criticising the statement of the Reform Association when he was called to order, but indications were afforded by his speech that the attitude of the Senatus towards the Association and its proposals would evidently be strongly antagonistic.

LUNACY IN VICTORIA.

THE report of the Inspector of Lunatic Asylums for Victoria for the year 1890 gives much interesting detail regarding the insane in that colony, which at the end of that year had an estimated population of 1,147,994. The admissions during the year numbered 729, or 75 more than in the previous year. Of those admitted, 581 are stated to have come for the first time under asylum treatment, and 148 had previously suffered from mental affection—viz., 112 once, 24 twice, 6 thrice, 2 four, 2 five, and 2 six times. On Dec. 31st, 1890, the registered insane, as compared with the entire population, bore the proportion of 1 to 304 In New South Wales there is 1 insane person in 377, in South Australia 1 in 410, and in England 1 in 341 of the general population. The report states that the high rate of insanity in Victoria can only be surmised, though various influences at work suggest an explanation. Chief amongst these are (*a*) the facilities offered by the lunacy system for safely and cheaply disposing of weak-minded persons who may have become a burthen to their proper guardians. The cost of medical examination of persons suspected of being insane, as well as of the transport of lunatics and their maintenance in the asylums, are largely borne by the State, not by municipal or district authorities, as in other countries. (*b*) The poor-house system of Britain has no equivalent in Victoria, and in so far is wanting an outlet for a large class of asylum inmates. (*c*) The standard of mental unsoundness in use leads to many persons suffering only from old age, and harmless as regards themselves or others, being certified as insane. (*d*) The mortality amongst patients has been low, resulting in an accumulation of the old and incurable. (*e*) A large number of the population follow nomadic pursuits, and so are especially exposed to some of the most potent causes of mental disease. The average number resident during the year was 3541—namely, 1954 males and 1588 females. The recoveries were at the rate of 39·25 per cent. of patients admitted, comparing unfavourably with the average of recoveries—43·08 for the past twenty-three years. The returns are regarded as showing that the number of incurable cases admitted was larger, and the recoveries were reduced by a larger number than usual being entered as "relieved." The mortality amounted to 7·45 per cent. of the average numbers resident, a slight advance on that for the past twenty-three years, which give 7·18 per cent. as the average. The boarding-out system was brought into force during the year, but the efforts in this direction proved in some measure abortive, the result rather tending to show that the social conditions of the colony would preclude any extensive application of the system. "People of moderate independence apparently shrink from the responsibility involved, and any considerable extension of the system could probably only be achieved at a prohibitory cost." Roughly speaking, about one-half of the inmates are able to work, and they are employed principally in farming, gardening, washing, sewing, and household work, and only a small number have shown any inclination to learn trades requiring skill. The idiot children number eighty-nine, and considerable amount of pains is taken to teach them as far as their condition will permit, object lessons, drill, and useful work constituting part of the training. There are about fifty criminal lunatics in the asylums, and attempts are being made to get separate and more suitable accommodation for this class of the insane, as "their association with other patients is open to manifest objection." In the various asylums classes have been formed where the warders may acquire special knowledge bearing on their duties, but many of the warders failed to take full advantage of the opportunities thus afforded them. However desirable it is that warders (all attendants) should submit to special instruction, we agree with the inspector in questioning the fairness of insisting upon the attendants acquiring a knowledge of psychology, physiology, and anatomy where there was no stipulation to that effect when they entered the service. Dr. Dick concludes with the following judicious remarks on this subject:—"The position would, perhaps, best be met by establishing a limited higher class of warders, admission to which should depend on the possession of certain attainments, to be tested by examination. It is not to be forgotten that some of the most useful and trusted attendants could not hope to bear such a test, and that, conversely, the ability to pass an examination would be altogether delusive as evidence that any particular person was trustworthy or possessed the tact, good nature, cheerfulness, activity, and other qualities essential in an attendant upon the insane." The cost of maintenance per week dropped from 12*s.* 2*d.* *per caput* in 1889 to 11*s.* 11½*d.* in 1890, this latter rate being further reduced to 10*s.* 8*d.* by taking credit for certain payments into the Treasury. Overcrowding is seriously complained of in the asylums as injuriously affecting the health of the patients, impeding management, and necessitating the occupation by patients of portions of the buildings never intended to be used in such a manner, and altogether unsuitable for the purpose. It is to be hoped that the Government will see the necessity as well as the advisability of taking steps ere long to remedy a state of things which not only hampers efficient administration, but also is an indirect source of expense to the colony by retarding recoveries.

THE ROYAL BRITISH NURSES' ASSOCIATION.

A MEETING of the General Council of this Association, summoned by command of the President (H.R.H. Princess Christian), was held at 20, Hanover-square on Monday, the 8th inst, to consider the advisability of proceeding to seek for incorporation by means of a Royal Charter.

Sir DYCE DUCKWORTH presided, and, in moving a resolution authorising the Executive Committee to act in the manner proposed, he said the Association ever since its foundation four years ago had accomplished a great deal of very valuable and good work, but not without exciting opposition in various quarters. Perhaps no good work had ever been carried out in this world without doing so. The Board of Trade had refused the application for registration under the Companies Act, and had shut its doors against them, and now the Association must either go backwards or forward to something else. He hoped the Association would go forward fearlessly, as it had nothing to fear, and in that true British spirit of determination which would take no refusal until something very near absolute success was attained. He believed this Association was pre-eminently fitted to do the work required to be done, and there were no other means which could help forward the Association in its work than by boldly applying for a Royal Charter which would enable it to fulfil all the purposes for which it had been designed, and without which the Association would fall short of its ideals.

Mr. BRUDENELL CARTER seconded the resolution They had practically been invited by the President of the Board of Trade to take some step by means of which the oppo-

Digitized by Google

sition to the Association might be unearthed and estimated at its proper value. They would not shrink from the challenge. All the objections urged against the registration of the Association were based upon statements absolutely erroneous, and nothing could be placed before the Privy Council which could afford any valid reason why this Charter should be refused.

Dr. BEZLY THORNE briefly reviewed the situation, and criticised the action of the President of the Board of Trade in assuming judicial functions, and, in so doing, in neglecting to perform one of the most essential duties of a tribunal—that of affording a hearing to both sides. The Association had no alternative but to adopt the suggestion of the Executive Committee.

This resolution was carried unanimously.

Dr. BEDFORD FENWICK said he had been asked to announce on behalf of her Royal Highness the President that she would be kind enough to make the application direct to the Queen in Council in her own name. The Association all over the world owed a deep debt of gratitude to her Royal Highness for what she had already done; and for this last mark of her interest in the work of the Association. Her steadfast determination to uphold justice to nurses would be welcomed and realised by the public as well as by the nursing profession.

Sir EDWARD SIEVEKING moved a resolution from the Royal British Nurses' Association, representing nurses in every part of Her Majesty's empire, expressing heartfelt sorrow with the Queen and the Prince and Princess of Wales in their recent bereavement. Her Royal Highness undertook to sign this address, and to forward it to the Queen and the Prince and Princess of Wales.

H.R.H. Princess CHRISTIAN then said: "At the time of my husband's sad accident I received much sympathy from the members of the Council and from the British Nurses' Association, and I have not had any opportunity of thanking them till now. I beg to return my warmest thanks and his at the same time."

Dr. PRIESTLEY moved a vote of thanks to Princess Christian for presiding, which was warmly accorded and graciously acknowledged.

Her Royal Highness afterwards moved a vote of thanks to Sir Dyce Duckworth for his conduct in the chair.

At the close of the business Mary Anne Sandford was elected first pensioner of the Princess Helena Pension for Nurses. Her Royal Highness then presided at a meeting of the Executive Committee.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

County Palatine of Durham.—Dr. Henry Armstrong has prepared a valuable summary for the Durham County Council on the reports of the medical officers of health for the forty-seven sanitary districts within their jurisdiction. For the twenty-three urban districts the mean mortality was 18·5 per 1000, for twenty-two rural districts it was 17·0 per 1000, the two remaining districts being ports. Spennymoor urban district, long a prominent one as regards faulty sanitary circumstances, takes the unenviable lead as to zymotic death, that rate being 3·4 per 1000. Notification of infectious diseases has not found much favour in the county, for only sixteen districts, including two ports, have adopted it, and only nine districts have as yet made any provision for the isolation of cases of such diseases. As in some other counties, reference is made to the want of uniformity in the plan of construction of annual reports, a want which prevents comparison as regards the several districts. Uniformity often tends to destroy the distinctive character of reports, and to reduce all to a common level; but there is no reason why, as regards the more important matters, there should not be some uniformity as to the subjects dealt with in the reports, and we understand that Dr. Armstrong only wishes uniformity in some such sense. Appended to a general introductory chapter, the report contains a summary account of the leading features attaching to each of the several sanitary districts concerned.

Stapleton Urban District.—This district had during 1891 a general death-rate of 18·0 per 1000, which exceeds that for any of the last ten years, and it is stated that epidemic influenza has been an important factor in bringing about this result, otherwise the ordinary zymotic rate was only 1·2 per 1000. The measures adopted to stay the spread of certain diseases, such as diphtheria, are recorded by Dr. William Brown, who also adverts to the prevalence of overcrowding in cowsheds, to the need for a public mortuary, to the desirability of extending the sewer system to localities where growth of population is taking place, and to the absence of any system for the compulsory notification of infectious diseases.

Aston Manor Urban District.—The general death-rate during last year was 16·9 per 1000. Though this is a trifle higher than the mean for the last ten years, it is rather lower than the rate for 1890, notwithstanding severe prevalence of influenza. As an instance of the class of preventive work going on in this district, it may be stated that during 1891 the number of scarlet fever cases reported was 337. No less than 236 houses were dealt with by stripping, cleansing, and disinfection; 242 lots of bedding and clothing were disinfected; and 124 of the patients were isolated in hospital. And as regards hospital isolation for all the infectious fevers, no less than 224 in all were so dealt with; indeed, the original hospital has been extended as its utility has increased. This and many other matters indicate excellent sanitary work, and good supervision of all that relates to the public health. We note especially that Mr. Henry May is taking proceedings with a view to action under the Housing of the Working Classes Act, 1890.

Chelmsford Rural District.—In a descriptive account of the general circumstances of this rural district, Dr. Thresh refers to the damming up of the river-water at Moulsham Mill outside the town of Chelmsford, and he incidentally notes the injurious consequences to which this gives rise. This bears out what we have recently contended, and it will afford surprise that Chelmsford can allow such a cause of ill-health to remain for so long a period without some real effort to remove it. The various sanitary circumstances affecting the whole rural district have been made the subject of careful study, and a commencement of work by way of distributing causes of death according to soil and topography generally has been made. Standing alone, it is found that as yet inferences are hardly capable of being drawn, but extension of such work might readily lead to valuable information. Many improved water-supplies have been obtained in the district, the housing of the labouring classes is receiving careful consideration, and in several localities the drainage and sewerage have been improved. The general death-rate for 1891 was 15·5 per 1000. The report is typical of what an annual report for such a district should be. It is comprehensive, and yet definite in giving information on all points of importance; and although it covers some fifty pages of printed matter, the author has found no reason for delaying its issue, as is so often done, until its interest and value have been greatly diminished by mere lapse of time.

Stroud Urban District.—Mr. Partridge reports a somewhat extensive outbreak of scarlet fever during the past year, and he explains how, owing to absence of information as to attacks and otherwise, measures of prevention were seriously limited. The hospital had to be closed, as had also the free library. Owing to diphtheria, flushing of sewers was resorted to, and this revealed the escape of sewer-air into houses, indicating the absence of proper means of aerial disconnexion. The general death-rate was unusually high—namely, 19·2 per 1000 living. Although a good public water-supply is available, and is generally in use, yet polluted and suspicious supplies are still resorted to by some. The discovery of these, but not the action taken, is reported, unless the latter comes within the description of improved water-supplies named in the sanitary inspector's appendix.

Bisley Urban District.—Closure of schools had to be resorted to in this district owing to measles, but apart from this, Mr. Partridge reports that zymotic diseases were not prevalent. The general death-rate for 1891 was 15·5 per 1000. A public water company are gradually increasing the number of their house connexions, and sanitary work generally seems fairly well maintained.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6622 births and 5106 deaths were registered during the week ending

Digitized by Google

Feb. 5th. The annual rate of mortality in these towns, which had been 35·4 and 32·1 per 1000 in the preceding two weeks, further declined last week to 26·2. In London the rate was 30·6 per 1000, while it averaged only 23·1 in the thirty-two provincial towns. The lowest rates in these towns last week were 13·8 in Bradford, 16·2 in Leicester, 17·1 in Leeds, and 17·4 in Halifax; the highest rates were 27·7 in Blackburn, 30·6 in London and in Portsmouth, 31·1 in Preston, and 39·6 in Norwich. The 5106 deaths included 440 which were referred to the principal zymotic diseases, against numbers declining from 604 to 455 in the preceding three weeks; of these, 240 resulted from whooping-cough, 72 from measles, 38 from diarrhœa, 36 from diphtheria, 31 from scarlet fever, 23 from "fever" (principally enteric), and not one from small-pox. No fatal case of any of these diseases was registered in Birkenhead; in the other towns the lowest zymotic death-rates were recorded in Leicester and Blackburn, and the highest rates in Preston, Sheffield, Salford, and Swansea. The greatest mortality from measles occurred in Liverpool, Derby, Wolverhampton, and Gateshead; from scarlet fever in Cardiff; from whooping-cough in London, Sheffield, Portsmouth, Salford, and Swansea; and from diarrhœa in Salford and Preston. The mortality from "fever" showed no marked excess in any of the large towns. The 36 deaths from diphtheria included 27 in London and 2 in Manchester. No fatal case of small-pox was recorded in any of the thirty-three great towns; 6 small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and 2 in the Highgate Small-pox Hospital on Saturday last. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 1274, against 1397 and 1329 at the end of the preceding two weeks; 101 new cases were admitted during the week, against 116 and 100 in the previous two weeks. The deaths referred to diseases of the respiratory organs in London, which had been 1465 and 1192 in the preceding two weeks, further declined last week to 761, but were 279 above the corrected average. The causes of 90, or 1·8 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Bristol, Leeds, Sunderland, and in nine other smaller towns; the largest proportions of uncertified deaths were registered in Leicester, Liverpool, Salford, and Sheffield.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 27·2 and 24·7 per 1000 in the preceding two weeks, further declined to 22·0 during the week ending Feb. 5th, and was 4·2 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 15·3 in Paisley and 18·5 in Dundee to 21·6 in Leith and 24·7 in Glasgow. The 612 deaths in these towns included 20 which were referred to whooping-cough, 10 to diphtheria, 8 to "fever," 8 to diarrhœa, 7 to measles, 2 to scarlet fever, and not one to small-pox. In all, 55 deaths resulted from these principal zymotic diseases, against 72 and 41 in the preceding two weeks. These 55 deaths were equal to an annual rate of 2·0 per 1000, which was 0·3 below the mean rate last week from the same diseases in the thirty-three English towns. The fatal cases of whooping-cough, which had been 24 and 16 in the preceding two weeks, rose again last week to 20, of which 10 occurred in Glasgow, 5 in Aberdeen, and 3 in Paisley. The deaths referred to diphtheria, which had been 9 and 4 in the previous two weeks, rose to 10 last week, and included 4 in Dundee, 2 in Glasgow, and 2 in Aberdeen. The 8 fatal cases of "fever" showed a slight further increase upon recent weekly numbers, and included 6 in Glasgow. The 7 deaths from measles exceeded by one the number in the preceding week; 5 occurred in Glasgow. The 2 fatal cases of scarlet fever corresponded with the number in the previous week, and included 1 in Greenock and 1 in Perth. The deaths referred to diseases of the respiratory organs in these towns, which had been 230 and 211 in the preceding two weeks, further declined last week to 173, but exceeded by 12 the number in the corresponding week of last year. The causes of 59, or nearly 10 per cent., of the deaths last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 54·1 and 41·5 per 1000 in the preceding two weeks, further declined to 33·6 during the week ending Feb. 5th. During the first five weeks of the current quarter the death-rate in the city has averaged 41·6 per 1000, against 38·1 in London and 22·0 in Edinburgh. The 225 deaths in Dublin during the week under notice showed a decline of 53 from the number in the preceding week, and included 3 which were referred to diarrhœa, 2 to whooping-cough, 1 to "fever," and not one either to small-pox, measles, scarlet fever, or diphtheria. In all, 6 deaths resulted from these principal zymotic diseases, equal to an annual rate of 0·9 per 1000, the zymotic death-rate during the same period being 2·9 in London and 0·8 in Edinburgh. The 3 fatal cases of diarrhœa exceeded the numbers recorded in recent weeks. The deaths referred to whooping-cough, which had been 10 and 5 in the preceding two weeks, further declined to 2 last week. Only one fatal case of "fever" was registered last week, against 5 and 3 in the preceding two weeks; this is the smallest number recorded in any week since August last. The 225 deaths in Dublin last week included 24 of infants under one year of age, and 76 of persons aged upwards of sixty years; the deaths both of infants and of elderly persons showed a further decline from the high numbers recorded in the preceding two weeks. Six inquest cases and 2 deaths from violence were registered; and 69, or nearly a third, of the deaths occurred in public institutions. The causes of 20, or nearly 9 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

THE death is announced of Patrick Sinclair Laing, Deputy Inspector-General, Inspecting Medical Officer of the Army and Navy Stores and Auxiliary, aged seventy.

Mr. J. Holt, Surgeon, 1st Bombay Lancers, was accidentally, while playing polo, thrown from his horse, and died a few hours afterwards from fracture of the skull.

ARMY MEDICAL STAFF.—Surgeon-Colonel Geo. Langford Hinde, C.B., to be Surgeon-Major General, vice Sir J. A. Hanbury, M.B, F.R.C.S.I., K.C.B, retired; Brigade-Surgeon-Lieutenant-Colonel Albert Augustus Gore, M.D., F.R.C.S.I, to be Surgeon-Colonel, vice G. L. Hinde, C.B.; Surgeon-Lieutenant-Colonel William Johnston, M.D., to be Brigade-Surgeon-Lieutenant-Colonel, vice A. A. Gore, M.D., F.R.C.S.I. (all dated Jan. 13th, 1892).

NAVAL MEDICAL SERVICE. — The following appointments have been made at the Admiralty:—Staff Surgeons: W. E. Bennett to the *Sans Pareil* and Michael Ronan to the *Alexandra* (both dated Feb. 9th, 1892); Stewart F. Hamilton to the *Durham* (dated Feb. 3rd, 1892); James Porter, for medical duties of ship and Bermuda Dockyard (dated March 4th, 1892). Surgeons: John P. J. Coolican to the *Belleisle* and Thomas R. Pickthorn to the *Vivid*, for Royal Naval Barracks (both dated Feb. 8th, 1892); John D. Menzies to the *Sans Pareil* (dated Feb. 9th, 1892); John L. Bagnall-Oakley to Royal Marine Artillery, Eastney (dated Feb. 10th, 1892).

MILITIA MEDICAL STAFF CORPS.—Hampshire Company: Surgeon-Captain William Collingridge, M.D., from the 3rd Division, Volunteer Medical Staff Corps, to be Surgeon-Major, and Surgeon-Captain William Wellington Lake, from the 1st Division, Volunteer Medical Staff Corps, to be Surgeon-Captain (both dated Feb. 6th, 1892).

VOLUNTEER CORPS. — *Rifle:* 2nd Volunteer Battalion, the Essex Regiment: Surgeon-Captain E. Shedd to be Surgeon-Major (dated Feb. 6th, 1892).—3rd London: Surgeon-Captain G. Hastings to be Surgeon-Major (dated Feb. 6th, 1892).

CHESTERFIELD HOSPITAL PENNY FUND.—At the annual meeting of the promoters of the above fund, held recently, a report was presented by the Committee of Management showing that £90 3*s.* 1½*d.* had been collected in the boxes at various places in the town, whilst Mr. H. Gilberthorpe, the secretary, received amounts during the year amounting to nearly £50. Relief had been granted in 329 cases. The committee are anxious to have a ward set apart in connexion with the Chesterfield Hospital for the treatment of medical cases, so as to avoid the necessity of sending such cases to other hospitals.

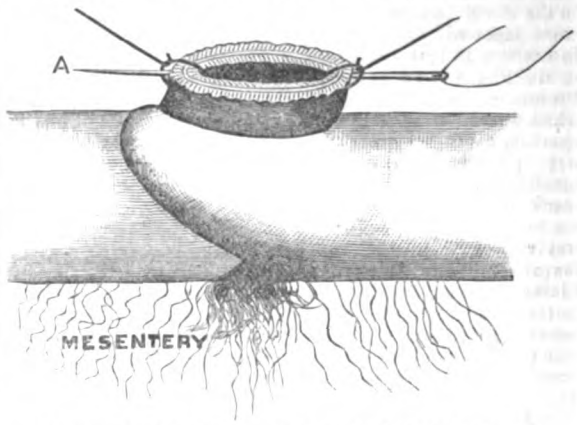
"Audi alteram partem."

ENTERECTOMY.

To the Editors of THE LANCET.



SIRS,—In THE LANCET of Jan. 23rd, 1892, p. 223, under the heading, "A Suggestion for the Treatment of Irreducible Intussusception of the Bowels," Mr. F. B. Jessett makes the following remarks:—

Mr. A. Barker will be interested to hear that last year, in conjunction with Dr. Morrotti, I made a series of experiments with a view of testing the feasibility of the operation. All these experiments, three in number, were successful. The steps I adopted were as follows: In the first place, I created an artificial intussusception, and allowed this to exist from six to ten days before operating for its relief; at the end of this time I found the invagination firmly adherent at the point at which the intussuscipiens receives the intussusceptum; the former was somewhat congested and œdematous. I made a longitudinal incision into the intussuscipiens on the side furthest from the mesentery, directly over the intussusceptum, about an inch and a half long, so as to allow of my being able to have a good view of and sufficient room to cut the intussusceptum across through the opening. I next seized the invaginated piece of intestine with vulsellum forceps and snipped it across about half an inch from the proximal end, catching up and tying any vessel that needed it, then with a series of interrupted sutures stitched the divided ends of the stump around, and returned it into the intestine, closing the longitudinal opening in the intussuscipiens with a double row of chromic gut sutures.

I am proud to learn that so excellent an authority on intestinal surgery as Mr. F. B Jessett now advocates the above operation. It is practically the same operation in every particular that I worked out and demonstrated eight or ten years ago in the Dunedin Hospital, Otago, New Zealand. I sent a notice of my paper on "Resection of the Intestine by a New Method" to the Intercolonial Medical Congress of Australasia, held in Adelaide, August, 1887. The notice was published at the Congress, but as I had a large number of surgical cases for that Congress I delayed the paper until the second Intercolonial Medical Congress, which was held in Melbourne, January, 1889. The paper begins with a description of a new bowel clamp devised by me. A short description of it appears in Treves' masterly work on "Operative Surgery," vol. ii., page 320. The following are extracts from my Congress paper on Enterectomy.

"When the entire circumference of the intestine is involved in a wound the bowel must be invaginated so as to bring the peritoneal surfaces into perfect contact all round, and suture them in that position. How is this to be accomplished? When nature performs enterectomy successfully, she invaginates the upper portion of the intestine into the lower, and when the peritoneal surfaces have united by adhesive inflammation the invaginated bowel sloughs off with impunity. Let us copy nature as closely as possible.

"These temporary ligatures are very important, as they secure the proper relative position of the two cut ends of the gut, and facilitate their subsequent invagination through the opening made in the larger segment of the gut. (See diagram.) If you examine the gut in a living animal, you will find the bloodvessels pass into it from the mesenteric attachment. These divide and subdivide, until they are lost in an invisible anastomosis in that portion of the intestine most distant from the mesentery. I propose to make an opening here in the larger segment of the gut, through which the invaginated ends of the divided bowel may be dragged by the temporary sutures, and when they are accurately sewn together all round they can be pulled back into their normal position. The longitudinal slit in the larger bowel, which begins about an inch from its transverse section, is brought together by a continuous suture. By this simple device the perfect union by suture of a complete transverse section of the bowel, with its peritoneal surfaces in exact position and all the knots of the sutures on the inside, can be accomplished. This opening should be made about an inch from the severed end of the larger bowel; its length depends on the size of the gut to be invaginated. In performing this part of the operation pinch up the coats of the intestine between the finger and thumb and transfix with a tenotomy knife. This operation is applicable to any part of the large or small intestine, and the pyloric end of the stomach may be excised in the usual manner and invaginated through an opening in the centre of the anterior wall of the stomach, sewn up from the inside, and then retracted to its normal position."

From this diagram it may be seen that the peritoneal surfaces are in accurate juxtaposition all round. While an assistant holds the ends of the temporary sutures, the surgeon passes a straight needle armed with stout horsehair through both sides of the bowel; the horsehair is then hooked up from the centre of the invaginated gut, divided, and tied on both sides. In this way twenty sutures can be placed rapidly in position with ten passages of the needle. The temporary sutures are now cut off short, the bowel pulled back, the longitudinal slit in the larger bowel closed with a continuous suture, and the mesentery brought together with four or five interrupted sutures.

In December, 1886, I first proved the ease and feasibility of my operation by successfully excising a cancer involving the entire calibre of the ileum to the extent of four inches. The case was a patient of D. Colquhoun, M.D. Lond., Lecturer on the Practice of Medicine in the Otago University, who very kindly handed it over to me for operation. Two operations were performed on this patient. The first operation, an exploratory laparotomy, revealed a mass of cancer, the size of a large lemon, involving the entire circumference of the ileum to the extent of four inches. As the mesenteric glands were enlarged and infiltrated with cancer, and the gut still slightly permeable, it was deemed unadvisable to attempt excision. The abdomen was completely drained of ascitic fluid and the laparotomy wound sewn up. For two weeks the child seemed wonderfully improved by the operation, which had relieved tension. At the end of the fourth week the bowels became completely occluded, and nothing was retained on the stomach. A consultation of the staff of the hospital was called, and, as there was complete occlusion, it was decided to remove the occluded portion of the gut. The steps of the operation were as follows:—(*a*) My sponge clamps were applied; (*b*) cancer excised; (*c*) smaller segment of gut invaginated into larger; (*d*) artificially created intussuscipiens longitudinally incised in that part most distant from the mesentery; (*e*) invaginated bowel brought outside and sewn up with interrupted sutures; (*f*) invagination retracted, and longitudinal incision closed by continuous suture. The time occupied in the operation from first to last was half an hour. I was assisted by Dr. Colquhoun, Dr. Batchelor, Lecturer on Gynæcology, Otago University, and Dr. Roberts, Lecturer on Pathology, Otago University. For the first three days after the operation the child seemed to be progressing favourably, there being little or no sickness. On the fourth day it got weaker, and sank on the sixth day after the operation. At the post-mortem examination the segment of bowel operated on was removed; union between both cut ends of the bowel had taken place; there was not the slightest sign or symptom of leakage.

In looking over my notes of the above case I find a short account of it, written by Dr. Colquhoun, read by me at the Medical Congress at Adelaide, 1887, in conjunction with my paper on Enterectomy. The limited space at my disposal here prevents me from inserting these notes. At a future date I hope to publish them in full. In the concluding remarks Dr. Colquhoun says: "The operation for resection of the bowel can be safely and speedily performed by the method adopted by Dr. Maunsell."

Last June I wrote a paper for the *American Journal of Medical Science* describing and illustrating (eighteen dia-

Digitized by Google

grams) my method of enterectomy for disease and injury in all parts of the intestinal canal. Dr. Sydney Coupland, the local editor, informed me that the very large number of diagrams had delayed its production, but that in all probability it will appear in the next number of the journal. In that paper will be found the following description of my operation in cases of irreducible invagination. "In all cases of obstruction from irreducible invagination where rectal hydrogen inflation in the inverted position under chloroform has failed to reduce the intussusception, perform laparotomy. Having found the intussusception, first try uniform compression of the invaginated portion and gentle traction of the bowel in the usual way above the neck of the intussuscipiens. If this fails, *instead of completely* excising the intussuscipiens with the intussusceptum, as is generally advocated, or diverting the invaginated block from the physiological functions of digestion and assimilation so ingeniously devised by Maisonneuve, proceed to resect the intussusception in the following manner. [A diagram is here introduced showing the intussusceptum dragged out through a longitudinal slit made in that portion of the intussuscipiens most distant from the mesentery, and one inch below the neck of the intussuscipiens.] Gently withdraw the intussusceptum until its neck appears outside the slit in the intussuscipiens; transfix the base with two fine, long, straight needles, armed with strong horsehair or chromicised gut. Now amputate the intussusceptum a quarter of an inch clear of the needles, so as to leave a fair stump beyond them. Transfixing the neck of the intussusceptum previous to its amputation prevents it from flying back inside, and ensures the proper relative position of the different layers of the bowel previous to sewing them up. Having amputated the intussusceptum, pass the needles through and pick up the suture in the middle of the invaginated bowel; divide it and suture the bowel on both sides; leave the ends of the four sutures long, so as to hold the cut ends of the bowel in position until it is completely sutured up circumferentially. Now cut off the long ends of the sutures. Apply Woefler's mixture of iodoform and compound tincture of benzoin, the same that he applies to the surface of the raw stump after removal of the tongue, and withdraw the bowel. It now only remains to sew up the longitudinal slit with a continuous suture."

I arrived in England last May. Since then I have explained the principles of my operation for enterectomy in injury and disease, and its application to all parts of the intestinal canal, to several prominent British and continental surgeons (including Mr. Jessett, whom I assisted to perform my operation on dogs), all well up in the literature of enterectomy. Not one of these gentlemen hinted that the principles laid down in my operation had ever been tried or suggested before.

I am, Sirs, yours truly,

H. WIDENHAM MAUNSELL, M.D,
Late Lecturer on Surgery, Otago University, N.Z.

Stanhope-gardens, Queen's-gate, Jan. 28th, 1892.

INFLUENZA.

To the Editors of THE LANCET.

SIRS,—At the discussion which took place some time ago on the above subject before the Medical Society of London, Dr. Theodore Williams asked me whether I could, in confirmation of my views on the pathology of influenza, point to any necropsies showing an unusual degree of hyperæmia at the base of the brain in such cases. I could not then answer his question in the affirmative, but have since seen a report of an epidemic in the Danish asylum of Aarhus, published by Helweg in the *Hospitals Tidende*, in which the results of eleven carefully performed post-mortem examinations are given. In all cases, without exception, there was found a most intense hyperæmia of the pia mater and brain such as is never seen in any other cases; and this was more particularly marked in the arteries at the base of the brain, which were filled with blood to bursting, and stood out as cylindrical cords, as if they had been injected with wax. The consistence of the brain and spinal cord was increased; in four cases there was also a fresh pachymeningitis, and in one case a fresh lepto-meningitis. It appears from this that the hyperæmia of grip is not simply an ordinary vaso-motor hyperæmia, but a process tending to produce inflammation, the latter, however, becoming only fully developed in particularly suitable cases. A relationship between influenza and epidemic cerebro-spinal meningitis is therefore clearly shown to exist. Although Hellweg has not specified the condition of the medulla oblongata in his cases, it is quite clear, from the description he has given of the arteries at the base of the brain, that intense congestion of that organ must have existed; and the suggestion thrown out by Dr. Sisley at the meeting of the Medical Society just referred to—viz., that the process might be one of anæmia rather than of hyperæmia—is therefore disproved. In any future post-mortem examinations of cases of influenza I would urge pathologists to give particular attention to the condition of the bulb and its vascular supply.

I am, Sirs, yours faithfully,

Harley-street, Feb., 1892. JULIUS ALTHAUS, M.D.

To the Editors of THE LANCET.

SIRS,—In referring to my article in the *Nineteenth Century* you say "it is to be regretted that Dr. Maclagan's conclusions were not submitted for discussion in the medical journals rather than in a lay publication, and without being encumbered with so much hasty and debateable material." May I point out to you that there is nothing in that article which has not, and mainly through the pages of THE LANCET, been submitted for discussion in the medical journals.

On March 29th, 1873, THE LANCET published a paper by me entitled "A New Theory of Fever," in which were embodied the views which, after nineteen years, it now calls "hasty and debateable material." Debateable it may be; hasty it is not. In 1875, in the course of a discussion on the germ theory of disease at the Pathological Society of London, I enunciated the same views in what THE LANCET was good enough to call "a valuable contribution to the debate." In 1876 I published a book on the germ theory of disease, in which "this hasty and debateable material" was fully placed before the profession. In the same year I published, again in the pages of THE LANCET, my original paper on the treatment of acute rheumatism by salicin, in which I gave to the profession the results of my researches on rheumatism. In 1881 appeared my book on rheumatism, in which these researches were more fully laid before the profession.

In 1887 I published, again in the pages of THE LANCET, a paper on pyrexia and hyperpyrexia; and in 1888 a book entitled "Fever: a Clinical Study," which was very favourably reviewed by THE LANCET, and in which will be found "the hasty and debateable material" to which it now objects. In 1890, during the first epidemic of influenza, I published in THE LANCET a paper showing the good results got from the administration of salicin in full and frequent doses in that disease.

When influenza reappeared I sent to THE LANCET a second paper on the same subject; it was not inserted. The expression of regret that my conclusions were not submitted for discussion in the medical journals hardly comes well from the journal which omitted to give me the opportunity of continuing the discussion in its pages.

I am, Sirs, yours faithfully,

Feb. 9th, 1892. T. J. MACLAGAN.

To the Editors of THE LANCET.

SIRS.—In the present flux of comments on the prevailing epidemic I have found it noticeable that little reference is made to the disease as occurring in young children. It seems certain that previous epidemics have varied much in the liability to attack in children and in the fatality from it in them. Thus in 1438 an Italian historian speaks of the large mortality in children from the disease. An epidemic in 1578 described by Ballonius may have been one of pertussis, as it chiefly affected children, but it was described as influenza. And similarly, in subsequent epidemics the greater or less tendency of children to be affected is described. Thus in 1782 it is noted that the disease was least prevalent and least fatal in children. And, generally speaking, I think the same may be said of our present experiences as was said in 1782. The disease in young children as seen by me has differed notably from the complaint in adults. One might reasonably expect to find a bronchial catarrh taking on the graver conditions of capillary bronchitis and broncho-pneumonia in a large proportion of cases, but such does not appear to be the result. The type seems to be that the onset of the disease may be fairly compared to that seen in scarlet

Digitized by Google

fever before the occurrence of the rash. But with this an increase in respiration and a dry, hacking, laryngeal cough supervene. No physical signs exist in proportion to the respiratory quickening. The child is torpid rather than in the uneasy condition common in this disease in older persons, and may or may not refuse nourishment. The pulse is somewhat quickened and asthenic in nature; the temperature ranges variably; the skin is dry or may be slightly moist; no profuse perspirations have been observed as a rule. After a few days the fever has gone, but the child is left in a depressed bodily state, and the cough often remains and frequently assumes the paroxysmal type seen in whooping-cough, and is frequently followed, as in pertussis, by vomiting. The temperature runs up occasionally at night, at which time also the cough is most persistent. I may say that this cough is about as amenable to treatment as is that of pertussis, in my experience. One case, in which a faint erythematous blush of skin existed, was in my opinion influenza.—I am, Sirs, yours faithfully,

Feb. 8th, 1892. ARTHUR THOMSON, M.B., D P.H. Camb.

To the Editors of THE LANCET.

SIRS,—In reference to your annotation in this week's issue of THE LANCET on Influenza in Children, I may mention that in this neighbourhood, though few children have been attacked, this winter the number of cases is greater than it was two years ago. One of the complications this winter, both in children and adults, has been the occurrence of otitis media. Of this I have seen no less than ten cases—seven in children and three in adults. In all the cases in adults and in four of the cases in children there was perforation of the membrana tympani, with serous or sero-purulent discharge. In two children and one adult both ears were affected. I do not know whether my experience has been exceptional, but, judging from the few cases of ear disease recorded, it would appear to be so. In THE LANCET for the last two years the only references I can find to this subject are: (1) A letter from Dr. Bronner of Bradford on March 8th, 1890; and (2) a paper on "Influenza and Ear Disease in Central Africa," by Dr. John Bowie, on July 11th, 1891. The cases I have seen are of the more ordinary kind mentioned by the latter, and not like the atypical cases mentioned by Dr. Bronner. As the complication is a somewhat serious one I venture to ask you to call attention to it. I should like to add that in the three years previously to last October I had seen only one case of otitis media in my practice; that occurred in 1890 during an epidemic of measles.

I am, Sirs, yours faithfully,

Feb. 10th, 1892. R. ACKERLEY, M.B. &c. (Oxon.).

To the Editors of THE LANCET.

SIRS,—As a constant reader and an occasional contributor to your pages for forty years, I may perhaps claim a right to put my *spoke* in this "wheel," or rather "woe," of mankind. In some hundreds treated by me with ten grains of soda salicylate and five grains of antipyrin, as long as pain and fever are present, followed by nux vomica, aromatic spirit of ammonia, and dilute phosphoric acid, as a recuperative tonic, with regular liquid nourishment every two or three hours, I have scarcely lost a case, and there are now five patients under my care whose average age is eighty-four years. I find tepid sponging, and when practicable a warm bath, great adjuvants to recovery.

I am, Sirs, yours faithfully,

Cley, Norfolk, Feb. 10th, 1892. W. SUMPTER, M.D.

A SANITARY MODE OF SPREADING DISEASE.

To the Editors of THE LANCET.

SIRS,—Would it be asking too much of our sanitary authorities if we were to request that they would themselves refrain from the systematic neglect of obvious precautions against the dissemination of disease? As matters of health are now dealt with, a very great wrong is being done to the community under cover of rendering it a service. When a complaint of the presence of sewer gas in any house or locality is made, the drains, and not uncommonly the sewers, are opened; but, so far as can be judged by results, no effective means seem to be adopted to prevent the contamination of the atmosphere by this disturbance. Surely, it ought to be a rule of practice among sanitarians that in the process of applying a remedy to existing evils, greater evils should not be created. A number of cases of typhoid fever have recently occurred in the metropolis and the suburbs in which the victims have distinctly contracted the malady when passing through public thoroughfares in process of disturbance for the purpose of repairing sewer pipes. Might it not be possible to saturate the earth, already probably poisoned, around a leaky sewer with carbolic acid or some other disinfectant before that earth is scattered with shovels on the surface of the roadway at the risk of infecting the neighbourhood? I am, Sirs, yours faithfully,

J. MORTIMER GRANVILLE.

Hanover-square, W., Feb. 8th, 1892.

"CONTAGIOUS SYMPATHETIC FEVER?"

To the Editors of THE LANCET.

SIRS,—There is a good deal of vague speculation at the present time, in both lay and medical journals, as to the *fons et origo* of the disease called influenza. Few are satisfied either with the name or with the treatment, and it goes without saying that if the former be empiric so must the latter be, and the profession and the public must be dissatisfied accordingly. It is therefore necessary to formulate a name which will at once express the disease and indicate the lines of treatment. It is with this object in view that I venture to classify the disease as a "contagious sympathetic fever." That it is contagious there can be no manner of doubt: the evidence is overwhelming, and the degree of contagion is in direct proportion to the cubic space of the dwelling and the number of its inmates. A large experience of the three epidemic periods of 1890, '91, and '92, amongst the ill-housed labourers of Dorset, has proved this to my own mind as clearly as a problem in Euclid. Whatever the nature of the poison, its strength and virulence are intensified by overcrowding, bad ventilation, and defective sanitation. In this respect it reminds one more of typhus fever than anything else; its sudden incidence, accompanied with high fever, frequent delirium, epistaxis, dusky lurid flush of the face, suffused conjunctivæ and bright shining, almost glassy, eyes, a not infrequent dull scarlet eruption, and occasionally bullæ on the feet and herpetic eruptions about the face, nose, and chest, all together point to the baneful action of some noxious poison which appears to gain entrance to the body and thence to the blood through the ordinary channels of respiration, and which at first stimulates and quickly depresses the heat-producing centre of the nervous system. So prompt and powerful is this primary stimulation if the poison be at all concentrated, that the reaction is immediate and profound. The initial headache is succeeded in from twelve to twenty-four hours by intense prostration, with muscular pains, chiefly of the lumbar region, but often general; and with these more crude manifestations of the second stage we have exhaustion of the involuntary muscular system, as seen in the heart-muscle and sometimes in the gastro-intestinal, when the latter is primarily involved. Were the disease out-and-out typhus fever, no doubt the initial fever would be more gradual and persistent, but as regards the resulting depression the similarity is beyond dispute, and the same treatment is required in both. There is nothing so marked in the present, and indeed in the recent, epidemics as the strongly "sympathetic" character of the complaint. From the very outset, the entire sympathetic chain appears to be involved, and this will go far to explain the visceral complications and the primary headache. Undoubtedly there is at first high arterial tension, but this speedily gives way, with or without treatment, and then succeeds the more dangerous period of local congestions and embarrassed circulation. It is towards the end of the first or the beginning of the second stage that fainting takes place, unless indeed the heart be already weak and gives way at the outset; so also is it about this time that cough supervenes, or it may be vomiting and purging. Thus we have a contagious sympathetic fever resembling typhus fever, which may prove abortive or follow the course indicated. The extent and variety of the sequelæ prove that individual proclivity and climatic conditions play an important *rôle* in the determination of the result. In fact, I believe, one might say with a strong degree of probability that most of the secondary symptoms of the disorder are due to the conditions named, to which might be added the age and habits of the individual. It is just as difficult to save an old and

Digitized by Google

decrepit man or woman from this insidious complaint as it is to cure a case of typhus fever above fifty or sixty years of age, and both are alike destructive to the weak and debilitated at all ages. Influenza (so-called) is not *per se* a grave disease to the young and strong, if ordinary care be taken; but to all others it is of fearful significance under all circumstances. Stripped of its sequelæ and its complications, it is a comparatively simple disease, and by no means difficult to treat if due care be taken to support the patient from the beginning of the second stage; nor is any special remedy wanted to cut it short, as it is essentially of short duration as a contagious sympathetic fever. Of course, this description ignores the quality of the contagion or poison. But to practical physicians this is of small account; and were the alleged germ or microbe demonstrated beyond question, and even an extract of it prepared for injection, it would be of little avail apart from those measures of prevention and cure which are within the reach of all.

I am, Sirs, yours faithfully,

London, Jan. 25th, 1892. ALEX. MCCOOK WEIR, M.D. &c.

"DEATH CERTIFICATES BY UNQUALIFIED ASSISTANTS."

To the Editors of THE LANCET.

SIRS,—Kindly allow me to make a statement in reply to some remarks concerning me that appeared in an annotation in THE LANCET of last week. It seems to me that those remarks are based on two assumptions, both of which are incorrect. First, I deny that Mr. Austerberry is, or has been, my assistant during the last twenty years, throughout which period I have never employed an assistant. Second, Mr. Austerberry has never had authority from me to attach my name to a death certificate, or to any document whatever, and that until a report of the inquest appeared in our local daily paper I was unaware that he had ever done so. I know nothing whatever of deceased, nor of the club to which she belonged, and I can conscientiously affirm that for many years I have never given a death certificate without having personally visited the patient. This statement should exonerate me from all responsibility as to the death certificate referred to.

I remain, Sirs, yours truly,

Hanley, Feb. 8th, 1892. ARTHUR GOODWIN.

*** We have great pleasure in publishing the above disclaimer, and sympathise with Mr. Goodwin in the annoyance to which he must have been subjected by the errors in the report which formed the basis of our remarks.—ED. L.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

Newcastle Royal Infirmary.

THE annual meeting of the Newcastle Infirmary was held last week, the Earl of Ravensworth presiding. The number of in-patients treated last year was 3295; the number of out-patients and casuals was 20,188. The number of deaths was 260, giving a death-rate of 7·89 per cent., but abstracting the deaths that took place within twenty-four hours of admission, the patients being moribund, the death-rate would be 6·19. A large number of cases of operation were of a very severe character, and such as a few years ago the ablest surgeon would have hesitated to attempt. Amongst other important abdominal operations there have been twenty-four for ovarian cysts, all the patients, with a single exception, having recovered. The financial state of the infirmary is, however, unsatisfactory, there being an excess of expenditure over income of about £2000 per annum. The workmen's subscriptions had amounted to £3200; the Hospital Saturday and Sunday Fund had contributed about £1100. Two large and special legacies had been received during the year—viz., £10,000 from the late Mr. John Fleming of this city, and £6000, being the larger part of the residue of the estate of the late Mr. Robert Walters, also of this city. With regard to a new infirmary building, the report goes on to say "that the committee, until they see their annual expenses met, cannot press upon the public the necessity which exists for a new infirmary, and yet they cannot forget it." The present accommodation afforded by the infirmary is insufficient, and even to lodge the nurses an additional house has to be maintained. There is no isolation ward, which causes great inconvenience and anxiety, and the cost of continued repairs is very considerable. A new infirmary adapted to present requirements, the committee believe, would cause an annual saving. It transpired at the meeting that the estimated cost of a new infirmary would amount to about £140,000.

Lead Poisoning.

An inquest has been held respecting a female worker at one of our white-lead factories. Her age was nineteen, and she had worked irregularly at the lead for about twelve weeks. She had previously been a strong, healthy girl. She left off work for a week, and seemed well on the Saturday before her death. On Sunday she was seriously ill, becoming insensible, and had convulsions, from which she died on the Monday morning. The evidence of the surgeon in attendance showed very clearly that the convulsions (epileptiform) and her death were due to lead poisoning, and the verdict was in accordance. Another inquest has since been held on a married woman aged thirty, a worker at the same factory. Her husband said she had always been a healthy woman until she went to the lead works, where she worked about five months. After she had worked there nine or ten weeks she had bad eyes, and complained of her head. The surgeon to the works said he attended her first last September for neuralgia of the head, and that when called to her on the Tuesday before her death she had frontal headache; he saw her again the same night, when she was in a state of stupor after a fit. He thought her death, which took place on the following Thursday, was due to convulsions, originating from some disease of the brain. He did not treat her for lead poisoning, as there were no symptoms of lead poisoning at all in her case, and a verdict was given in accordance with the medical evidence. I always record cases of death where lead is the suspected cause in these notes. After all precautions are taken the loss of life to the female workers in the factories is very great, and of course it will continue until this labour is abolished; and the sooner this is done the better.

Durham County Hospital.

At the annual meeting of the Durham County Hospital, held last week, the report stated that 349 in-patients had been treated during the year, and 1098 out-patients, including 231 casualties. The financial state of the hospital was satisfactory. A discussion took place on the want of interest taken in the hospital by the general body of subscribers, and amongst other suggestions it was mooted that the hospital should be made free, and the ticket system abolished. Matters seem to be working now in this direction amongst many of our northern hospitals.

Sunderland: Remarkable Longevity.

During the week ending Jan. 30th 47 deaths have been registered as having occurred in the borough of Sunderland, giving a mortality of 18·5 per 1000. Of 16 deaths in the Bishopwearmouth south district, 7 resulted from old age, the aggregate number of years being 566, with an average of 80·6. The ages of 5 others who died in the remaining districts of the borough amounted in the aggregate to 367, with an average of 73·2. There have been no deaths from influenza during the past week.

Death of Mr. Henry Featherstonhaugh, M.R.C.S., late of Newcastle.

Mr. Henry Featherstonhaugh, formerly in extensive general practice in Newcastle, but who retired many years ago, died on the 1st inst at his residence, Ravensworth-terrace, Gateshead, of pneumonia, after two days' illness. Mr. Featherstonhaugh was formerly house surgeon at the Gateshead Dispensary, and was well known and respected on both sides of the Tyne. He was in his seventy-seventh year, and has left a widow, but no children.

I am pleased to say that Dr. Heath of this city, whose serious illness was reported in our local papers a short time ago, is now very much better. He has been seen by Mr. Page and Dr. George Murray.

Newcastle-upon-Tyne, Feb. 10th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Professor Crum Brown and the Statement of the Association for the Reform of Medical Education.

PROFESSOR CRUM BROWN has considered it his duty to write a letter to the chairman of the Universities Commission on the statement submitted by the Association for the Reform of Medical Education, and he has had the courtesy to circulate copies of it. Only two paragraphs of the letter need be quoted here, for the enlightenment of old Edinburgh students. He says: "The lecturers who have signed the document presented to the Commissioners have given a novel definition of lectures. They tell the Commission that lecturing consists in the dictation of the details of the subject. Of such lecturing it is no question as to how much or how little of it there ought to be; it is clear that there ought to be none. I understand by lecturing something very different from this. The duty of a lecturer is to present to his students a clear, well-arranged, well-balanced exposition of the principles of the science he teaches, illustrating the application of these principles by means of well-chosen examples. This is a high ideal, but one to be aimed at. If lecturing degenerates into the reading of a published or unpublished text-book, it ceases to be true or efficient lecturing. A lecturer or professor who dictates the details of his subject to his students does not do his duty, and the cure is not to give him less of that bad work to do, but to relieve him of it altogether and set him on the right road." The question which these sentences suggest is, Did his colleagues see this letter? To old students and those connected with, or who know the springs of things in, the school there is a charming simplicity and individualism in the opinions which, if accepted by the school at large, would do much to obviate the necessity of reform associations.

Proposed Extension of the Royal Infirmary, Edinburgh.

Negotiations have been reopened between the Royal Infirmary and the managers of the Sick Children's Hospital and the Merchant Company, to ascertain if arrangements cannot yet be come to for the acquisition of ground more suitable for the purposes of extending the buildings than the plans recently suggested and referred to here.

Health of Edinburgh.

The mortality last week was 100 and the death-rate 20 per 1000. Diseases of the chest accounted for 50 deaths and zymotic diseases for 4. The intimations for the week were: typhus fever 2, typhoid fever 1, diphtheria 5, scarlatina 24, and measles 30.

Feb. 9th.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Irish Colleges' Conjoint Scheme.

THE following is an outline of the five years' curriculum for the diploma in Medicine, Surgery, and Obstetrics of the combined Colleges, as agreed to by the Committee of Management:—First year: (1) Demonstrations and Dissections, six months; (2) Practical Chemistry, three months; (3) Practical Pharmacy, three months; (4) Lectures, (*a*) Physics, (*b*) Elementary Biology, (*c*) Theoretical Chemistry, each six months. Second year: (1) Hospital, nine months; (2) Demonstration and Dissections, six months; (3) Lectures, (*a*) Anatomy, six months, (*b*) Physiology, six months, (*c*) Histology, three months, (*d*) Materia Medica, three months. Third year: (1) Hospital, nine months; (2) Demonstrations and Dissections, six months; (3) Lectures, (*a*) Medicine, (*b*) Surgery, six months each, (*c*) Forensic Medicine and Hygiene, (*d*) Pathology, three months each. Fourth year: (1) Hospital; (2) Midwifery Hospital, including Diseases peculiar to Women and to Newborn Children, if not deferred to fifth year, six months; (3) Operative Surgery, three months; (4) Lectures, (*a*) Midwifery, six months, (*b*) Mental Disease, three months. Fifth year: (1) Clinical Study in recognised British or Foreign Hospitals, nine months, including (*a*) Surgery, (*b*) Medicine, (*c*) Ophthalmic and Aural Surgery, (*d*) Fevers; (2) Midwifery Hospital, unless taken in fourth year, six months; (3) Vaccination. As contrasted with the existing four years' course, there are some changes and additions. For example, only one course of anatomical lectures will be required instead of two; but attendance on lectures will be required during the first year on physics and elementary biology, six months each. A three months' course of lectures on mental disease will be obligatory, a certificate for vaccination, and during the fifth year nine months clinical study in hospital. Attendance on fever cases and in ophthalmic hospitals is transferred to the fifth year, while hygiene is not made a separate course from forensic medicine, as was expected, but is combined with that subject, contrary to the regulations of the English colleges. Requiring attendance on lectures on mental diseases is a step in the right direction—that is, if the lectures are clinical lectures delivered in a hospital for the insane, otherwise they would be useless, and a mere waste of the student's time and money. Of course this is only a draft report of the Committee of Management, and has to be considered by both Colleges.

Typhoid Fever in Dublin.

Mr. Maguire, who has had great experience as a sanitary engineer, has lately reported to the Public Health Committee of the Corporation, of which he is a member, on the subject of the prevalence of typhoid fever in Dublin and its possible prevention. He is of opinion that the city may be freed from its unenviable pre-eminence in epidemics of typhoid fever by carrying out the following reforms: 1. A main drainage system to purify the Liffey and the lower gravel subsoil now saturated with sewage. 2. A thorough reconstruction or renewal of all street sewers now imperfect in section, size, gradient, or level, or which may allow of leakage of sewage into subsoil. 3. A thorough reconstruction and renewal of all connecting house drains from houses to public sewers which are now allowing the escape of sewage into subsoil, or sewer air into houses which are not laid on concrete foundations having sufficient even gradient, which are too large in section to flush thoroughly or liable to become choked by any defects, or which pass from one house under any portion of another house. 4. The provision of proper intercepting traps, with easy access for inspection and cleansing, on every house drain, placed in the open areas where such exist, or otherwise in the most suitable sanitary position where the street-connecting drain enters the premises, always provided with fresh air inlet or outlet arrangements. 5. The proper construction and arrangement of all internal sanitary fittings, pipes, and drains. 6. The impervious paving of all stables, stable yards, dairy yards, and cowsheds, back yards, lanes, and streets, and the constant efficient cleansing of the same to prevent soakage of filth into subsoil. 7. The abolition of all privies, ashpits, and manure heaps. 8. The constant rigid inspection of all dairies and farm yards, and the effectual prevention of all infection therefrom. 9. The maintenance of the purity of the water-supply and distribution.

National Hospital for Consumption.

The general meeting of the supporters of this movement will be held on Wednesday, the 17th inst., in the Hall of the Royal College of Physicians. The meeting will be presided over by Dr. J. M. Finny, president of the College.

The annual meeting and dinner of the Dublin branch of the British Medical Association will be held at the College of Physicians on Thursday, the 18th inst.

Mr. W. I. Wheeler, F.R.C.S.I. &c., was last week sworn in as High Sheriff for the County of Kildare.

Feb. 9th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Septic Broncho-pneumonia of Intestinal Origin.

SEVESTRE, speaking on this subject at a meeting of the Société Médicale des Hôpitaux, held on the 22nd ult., reminded his audience that, in calling attention to these cases five years ago he had formulated the following conclusions:—1. In badly nourished children the intestinal contents may undergo decomposition, the products giving rise to fetid diarrhœa and septic enteritis. 2. This morbid condition may be the starting-point of general infection, revealing itself clinically most commonly by pulmonary congestion and broncho-pneumonia. 3. The best means of

Digitized by Google

combating the diarrhœa and preventing the lung complications consist in the exhibition of such intestinal disinfectants as calomel and naphthaline. (To this list M. Sevestre would now add naphthol, betol, and benzonaphthol.) The above conclusions were based on clinical grounds only. M. Sevestre announced that M. Lesage was now prepared to endorse them from a bacteriological point of view. This observer stated, in effect, that he had proved the exclusive dependence of broncho-pneumonia occurring in the course of septic enteritis on the presence in the lung tissue of the bacterium coli. There had been examined five cases in which pulmonary lesions, together with swelling of the spleen, had been noted during life. In one instance there was found post mortem intense generalised congestion of the lungs, which floated in water, became paler, and soon resumed their normal tint. Microscopical examination revealed the presence of the bacterium coli. In one of the lungs, islets of broncho-pneumonic consolidation were found enclosed in the congested tissue. In another case the broncho-pneumonic process had reached the suppurative stage. In these consolidated areas the bacterium coli was found to the exclusion of all other micro-organisms. Inoculated into animals, its virulence proved to be identical in degree with that of the same micro-organism as found in its usual habitat, the intestine. The bacterium derived from the suppurating nodules had acquired pyogenic properties, for its introduction into the areolar tissue of the rabbit and the guinea-pig provoked the formation of a local abscess, followed by death in four or five days. M. Lesage also discovered the bacterium coli in the air of wards occupied by several children under treatment for septic enteritis, as also in the sterilised milk supplied to the little patients and to their neighbours in the same room. The bacterium was found to be growing in the milk as a pure culture. The above interesting facts lead M. Lesage to recommend the isolation of these little enteritic patients in special wards. While admitting the important part played in this class of cases by the bacterium coli in the production of the above-mentioned pulmonary complications, M. Sevestre does not feel justified in attributing to this microbe the exclusive *rôle* claimed for it by M. Lesage. Accepting as true the contamination of the milk, even previously sterilised, supplied to a large children's ward, he is of opinion that such a mishap may be best averted by the hospitalisation of the infecting patients in a number of small wards. Alluding to the suggestion advanced by M. Comby, that the stools be disinfected by means of cupric sulphate or corrosive sublimate, M. Sevestre pointed out some practical difficulties, in that the motions are often passed, not into bed-pans, but into the bed. I fail to see why the same disinfecting process should not be applied to the bed linen. This discussion seems to point to the fact that, in future, greater attention must be paid to intestinal antisepsis than has hitherto been the case, if we wish to avoid complications which too frequently prove fatal, not to mention the infection of patients under treatment for other diseases who may be occupying contiguous beds.

The Nerve-compression Treatment of Hiccough.

Every practitioner has met with cases of hiccough which seem to resist all known methods of treatment. As the continually recurring spasmodic contraction of the diaphragm is not only highly distressing to the sufferer, but may, through the exhaustion it produces, be the immediate cause of death, it is a matter of importance to be acquainted with a ready, speedy, and sure method of controlling this symptom. In many instances it is probably due to the presence of unabsorbable fluid in the stomach, and the rational remedy is an emetic, preference being given to apomorphine administered hypodermically. When, however, hiccough occurs as a neurosis, an infallible remedy is found in digital compression of the phrenic nerve, if we may believe M. Leloir (Acad. des Sciences, 18th ult.). This is not at all a new idea, for it is mentioned by several English authors. But the somewhat extensive experience of the method possessed by M. Leloir is worth recording. That gentleman tells us that five years ago a girl of twelve was brought to him in order to be treated for incoercible hiccough which, recurring every half minute, had lasted for one year, and had, as may be imagined, greatly interfered with sleep and nutrition. M. Leloir applied digital compression for the space of three minutes to the left phrenic nerve in the interval between the heads of origin of the sterno-cleido-mastoid muscle, and definitely cured his patient, who had previously tried all the known anti-spasmodics of the codex. M. Leloir has since successfully applied his method in a large number of cases of chronic and recent hiccough which had proved refractory to other remedies. He states that he has not met with an instance in which this compression, exercised for a few minutes—sometimes only a few seconds—did not prove effectual.

The Microbe of Influenza.

In 1890 Babès recorded having observed in cases of this hydra-headed scourge a small organism resembling in form the diplococcus, from 0·2 μ to 0·3 μ in diameter, forming in gelose pale, transparent cultures. A little later Kovalsky, as the outcome of his researches in the same field of inquiry, obtained somewhat similar results. More recently Pfeiffer of Berlin, and contemporaneously with him Canon, confirmed by independent inquiries the foregoing. According to these latter observers, the blood of persons affected with influenza contains a special bacillus, which they consider to be the *materies morbi* of this disease. In this country the research for the hidden bacteriological entity of this curious epidemic is not less ardent than abroad, and the secret bids fair to be yielded up in full view before long. Yesterday, at the Academy of Medicine, M. Cornil, in conjunction with M. Chantemesse, made an interesting contribution towards this end, of which I transcribe the salient points. A drop of blood was taken from an infant, the subject of influenza, and inoculated into the vein of a rabbit (No. 1). The day after the blood of the rabbit was found to contain microbes responding to the description of Babès and Pfeiffer, very small and more difficult to be seen than those found in septicæmia in the same animal, but capable of being stained by methylene blue and fuchsin in Ziehl's solution. In length they measure about one-twentieth the diameter of a red blood disc. The blood of the animal inoculated on sweetened gelose gave characteristic cultures and became surrounded at the expiration of twenty-four hours by an opaline zone which, under a magnifying power of 100 diameters, gives the appearance of very fine granules. The cultures, when stained and examined under the microscope, displayed the same micro-organisms as those found in the blood itself; they appear free, or in little agglomerations, or enveloped in small particles of gelose. These cultures were used to inoculate another rabbit (No. 2), the blood of which contained a bacillus similar to that from which the cultures were procured. This bacillus was easily cultivated in sweetened bouillon. From the rabbit the virus was transferred to a monkey. A few drops of the bouillon culture were placed in the nasal fossæ. It is probable, however, that this injection penetrated into the pharynx and was swallowed, for the symptoms presented later by the monkey were diarrhœa, fever (38·5–39·5 C.), weakness, with tendency towards sleep—symptoms which lasted several days, and were followed by depression and subnormal temperatures. These same micro-organisms were found in the sputa as well as in the blood of several patients attacked with influenza, not only during the climax of the febrile state, but for days after the fall of the temperature. A little blood from one of these patients, a young woman, the subject of uncomplicated influenza, was injected into a vein in the ear of a third rabbit, which the following day manifested the same symptoms, elevation of temperature &c. observed in the others, and in the blood of which the same bacillus was found in abundance. These observations, therefore, of no less an authority than Professor Cornil and his collaborator confirm in essential details the researches of Babès, Pfeiffer, and Canon, and lead them to the conclusion that influenza is an infectious disease caused by the bacillus in question, which by its form, its culture, and its reaction to staining agents they believe to be the micro-organism special to the universal malady. The disease, as manifested in the rabbit, is not of a severe type but of somewhat long duration. These animals grew thin, lost appetite, and were found to contain in the blood for over three weeks the bacillus in abundance. M. Cornil adds that the bacteriological researches hitherto made in connexion with influenza and other microbic affections go to show that the presence of the former strongly predisposes to infection from one or other of the latter, and hence the variety of complications. As to the bacillus itself, they repeat that it is not easy to distinguish it owing to its minuteness and the difficulty of staining it. It cultivates slowly at 37c. in gelose or in sweetened bouillon, and readily lends itself to re-culture in artificial media. At the expiration of twenty-four hours the culture in gelose appears as a very fine pink, cloud-like outline. In bouillon the

Digitized by Google

culture is scarcely visible to the naked eye. These media preserve their transparency in presence of the culture, but interspersed here and there with very fine granules. In concluding this notable contribution to the pathology of influenza, MM Cornil and Chantemesse express the hope that the discovery of the micro-organism will go far towards perfecting our study of the diagnosis, the prophylaxis, and the treatment of this disease.

Epidemic of Rabies.

What is described as a veritable epidemic of hydrophobia has appeared amongst the domestic animals in the Commune of Pepieux in the arrondissement of Carcassonne. As many as forty of these animals, including dogs, cats, and even sheep, have been put to death. Several accidents to persons are mentioned. A man of thirty-five was bitten, and is now under treatment at the Pasteur Institute. The Mayor of Pepieux has ordered that all dogs be put under observation for forty days. At Ventenac d'Ande, in Narbonne, a mad dog has bitten two young girls of fourteen and fifteen. The animal was then allowed to escape to a neighbouring village named Bize, where it bit another victim. It finally escaped back to its home at Ventenac, and was not put to death before it bit two of its master's servants. All these cases are under treatment at the Pasteur Institute. There is considerable excitement in the locality, where naturally the result of the treatment is anxiously awaited.

Tuberculin.

THE rumour that Koch will publish a new article very soon on further progress made by him in the perfecting of tuberculin is denied on good authority. The fact of his continued unwearied efforts to that end, however, is confirmed.

An Alleged Cure for Cancer.

Professor Adamkiewitsch of Cracow, who has been experimenting in Vienna with a remedy for cancer for months past, has showed the Society of Medical Men there a patient who, he says, has been completely cured by the process. He stated that the glands, which had been slowly but steadily growing for half a year, had completely disappeared after a fortnight's treatment. The cure took place under the influence of injections which have no effect on other than cancerous formations. He maintained that the efficacy of his remedy is now beyond doubt, but Professors Billroth and Kundrat controverted the statement that the remedy is an absolutely certain one.

Antinervin.

The alleged efficacy of a new medicine largely used against influenza in the recent epidemic in Glogaw has attracted the attention of the medical world here. Its name is antinervin. It almost always alleviates the pains in the head and back, has been observed to cause a rapid reduction of the fever, with copious perspiration, and no unfavourable effects have been traced to its administration. Eight powders of half a gramme, taken in two days, generally sufficed to arrest the disease. It is about five times cheaper than antipyrin. It has been tried in the Royal Clinics of Turin and Genoa, and the heads of these establishments report favourable results.

The Berlin Society for the Cure of Mental and Nervous Diseases celebrated its twenty-fifth anniversary yesterday.

Dr. Heinrich Rosenthal, editor of the *Allgemeine Medizinische Zentralzeitung* (*General Medical Central Journal*), died here on Feb. 7th, in his fifty-eighth year.

NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

A Secretary of Public Health.

WITH the opening of Congress there is a renewal of the agitation for a National Public Health Service. There is certainly great need of definite legislation on this subject, for at present that service is in a very anomalous state. There is in existence a National Board of Health without either power or means to do active work. There is the Marine Hospital Service, a bureau of the Treasury Department, to which is assigned limited power relating chiefly to quarantine, and which can expend the contingent epidemic fund under the direction of the Secretary of the Treasury; but there is no well-defined Public Health Service with adequate powers and means such as a nation should have which is exposed on every hand to the invasion of foreign pestilences capable of prevention by a thoroughly organised and equipped Department of Health. The present movement to secure legislation is undertaken by the American Medical Association, and it promises to unite and concentrate upon this great question the energies of the entire profession of the country. The form of central organisation which the Association proposes is a Department of Public Health presided over by a secretary, who shall be a member of the Cabinet. The ideal of the Association is certainly very high, and, it is to be feared, quite unattainable at this time. There is a strong prejudice against increasing the number of departments of the general government, and it is too true that the people are as yet far from realising the value of a department devoted to the protection and promotion of the public health.

The Pan-American Medical Congress.

The movement to assemble an American Medical Congress, composed of representatives from all nationalities of the Western hemisphere, during the Columbian Exposition, 1893, is progressing very satisfactorily to its projectors. A committee on organisation has been created which contains representatives from nearly every county in North and South America, and nearly all of the West India Islands. The correspondence of the local committee shows a hearty cooperation of the profession of these countries in the undertaking.

An Important Decision in a Suit for Malpractice.

A man who had been operated upon at the New York Hospital brought a suit against that institution for alleged ill results. On trial the question raised was as to whether the surgeon had performed the operation skilfully, and a verdict was rendered in favour of the hospital. Subsequently the same person brought a suit against the surgeon on the same grounds. The judge decided that the plaintiff had no standing in court, remarking, "It seems to me, upon every principle, that it is in the interests of justice, and in accordance with public policy, that after a man has had his day in court, and has been granted and accorded every opportunity of fully and fairly presenting his case, and after he has made his election and tried his case, he should not be allowed to come into court and try the same question over again."

New York, Jan. 26th.

Obituary.

SIR GEORGE EDWARD PAGET, K.C.B., M.D., D.C.L., LL.D., F.R.S.

IF there were any need of evidence as to the great esteem and affection, we might say veneration, in which the late Professor of Physic in Cambridge was held it was amply shown by the large attendance at his funeral on the 4th inst., when, at the service in his College chapel, where he had for so many years been a regular attendant, the Bishop of the diocese, the Vice-Chancellor, and practically all the heads of houses, professors, and resident members of the Senate, besides many friends from a distance, were present; and he was followed to the grave by numbers who could not gain admission to the chapel, including all, or nearly all, the medical men of the town. All bore witness to the loss of a common friend, of a highly gifted and eminently upright man, who had devoted a long life unceasingly, energetically, and in the best spirit to the interests of the University, the medical school, the medical profession, and the town and neighbourhood of Cambridge. He combined in a high degree and in a very unusual manner the somewhat opposite qualities of accuracy and precision and their natural associates—truthfulness and conscientiousness—with the facility of arriving at correct results, great acuteness and rapidity of decision, with clear, calm, far-sighted judgment. Few men can so quickly seize upon and so forcibly expose the weak points, the flaws, in a pro-

Digitized by Google

posal or an argument as he was wont to do, a power which was attributable to his possessing in a pre-eminent manner the faculty of quick, close attention—the faculty, that is, of bringing his mental batteries to converge at once on the subject before him. Hence his opinion, though speedily formed, was carefully formed, not easily changed, and not often wrong.

No wonder that he was so highly regarded and confided in by his University, that he was elected and re-elected a member of the Council of the Senate and of the General Board of Studies and on many syndicates; no wonder that his influence was so great in promoting that development of the natural science and medical schools which has been a striking feature in the recent life of the University. To the qualities above mentioned he added a genial, kindly, friendly disposition, which grew with his advancing years, and a high, dignified, gentlemanly bearing which never deserted him or was thrown off its balance. Altogether he was an admirable representative of the University and the profession, combining the best features of both; and the members of both could feel that on all occasions their interests were safe in his hands. His great qualities evinced themselves also in the practice of his profession. He was a first-rate physician, and universally acknowledged to be so—conscientiously accurate in investigation, careful in diagnosis, shrewd in estimation of character, and judicious in treatment, leaving no detail uncared for. Decided, yet kind and considerate, he won the confidence of practitioners and patients, and bore the palm, without a rival, in practice in the University town and county till a late period of life. Not setting up to be an orator, he spoke clearly, saying well, vigorously, and emphatically what he intended to say, waxing warm, with flashing eye, when upholding the interests of the medical school or his profession against the opposition which he sometimes had to encounter. His last speech in the Arts School, not many days ago, when inveighing against a plan for ceding the site of the medical school-building for another purpose, will not be forgotten by those who heard it. On less important and on more convivial occasions he never failed to interest and amuse his audience by the amount of his knowledge and life experiences and by those stories and anecdotes and personal narratives of which he had so inexhaustible a fund, and of which he was so good a teller. Social by nature and with a keen sense of the humorous, and a large store of it in himself, he thoroughly appreciated and enjoyed to the full the society which a university town affords, and belonged to several clubs which lose in him one of their most animated and agreeable members. In general politics he was a decided Conservative; in University politics he happily took on the whole a liberal view, and was in favour of advance, of increase of the range of teaching, of better remuneration of teachers and examiners, of contributions from the College funds for the purpose, of extension of University influence, and of many other changes that have taken place. He was also one of those who, in the recent discussions, expressed the decided opinion that both the dead languages ought no longer to be made compulsory subjects of examination for all students who enter the University.

He watched with brotherly pride the rising career of Sir James Paget, who rarely took an important step in life without seeking advice from him; and the happy relations between the two often gave to members of the University the opportunity of seeing and the delight of hearing the renowned and eloquent surgeon. The last occasion was the Founders' day at King's College, Dec. 6th, 1890, when both were present, and Sir James, in his never-failing charm of style, replied to the toast of the visitors, and alluded in feeling terms to the advantage he had through life derived from the wise counsel of his elder brother. The two present not a few reminders of William and John Hunter; and since the time of those illustrious men no brothers have risen to such eminence in the respective branches of their profession.

Sir George Paget was the seventh son of Mr. Samuel Paget, a merchant at Yarmouth, and was born on Dec. 22nd, 1809. His early education was at the Charterhouse, and he was entered at Caius College in 1827, a contemporary and life-long friend of Professor Selwyn. It may be mentioned that an elder and a younger brother of his were also members of Caius College, and that the younger held a fellowship and College living. Sir George Paget pulled in the College boat, enjoyed his undergraduate life, and did not claim to have been a hard worker, but came out eighth wrangler in 1831, the same year with Dr. Budd, subsequently physician to King's College Hospital, who was at the same College and third on the list. He was elected in 1832 to one of the two fellowships which at that time were given to those who, being natives of Norfolk, should qualify in medicine. He graduated as M.B. in 1833, and as M.D. in 1839. The mastership of the College was then also assigned to a Norfolk man; and had the then master, Dr. Davy, who died in 1839, lived a few months longer, Paget (then and always a great favourite in the College, and acting as College bursar) would in all probability have succeeded to the mastership and have lived the comparatively quiet life of the head of a house, devoting his talents and energies more exclusively to the business of the College and of the University. As it was, he threw himself into the practical work of the profession with greater success than any of his predecessors in Cambridge. In 1851 he relinquished his fellowship, and with it the prospect of the mastership of his College, by marriage with Clara, daughter of Thomas Fardell, L.L.D., Vicar of Soham, and took a house in the town. They had several children, and Lady Paget survives. In 1881 his close connexion with the College, to which he was greatly attached, was renewed by his election to a professorial fellowship under the new statutes. This gave him, he said, as much pleasure as his earlier election in 1832, and he held this fellowship till his death. In 1841 he was elected physician to Addenbrooke's Hospital. The vacancy took place intentionally during his absence on the Continent, but the activity of his friends defeated the plan and secured the election for him. He immediately commenced clinical teaching and clinical lectures, which had not been done before, and thus brought the hospital more distinctly than had previously been the case within the range of university study. It was through him also that clinical examination at the hospital was instituted as part of the test in the examination for medical degrees and licence to practise, and it was a worthy source of pride to him that Cambridge was thus placed in the van of effecting this important addition to medical examinations. He resigned the office in 1884, but continued to take a warm interest in the affairs of the hospital, and seldom failed to attend and take part in the meetings of the governors; and during the whole period of his connexion with the hospital an unbroken harmony was maintained between the governors and the medical staff. An excellent marble bust of him by Wiles of Cambridge, raised by a subscription headed by the Prince of Wales, was presented to the hospital, and stands in the entrance passage as a memorial of the long and good work he did there.

In 1864 he was elected, without opposition, representative of the University on the General Medical Council. The best evidence of his good work there is afforded by the fact that he was chosen by the members of the Council to be their President in 1869; and his courtesy, good judgment, and discretion, together with the admirable manner in which he conducted the business of the Council, rendered his resignation of the office in 1874 a source of universal regret. About this time he was urged to come forward for the Presidency of the College of Physicians, and there was every reason to suppose that he would have been elected; but he declined to do so, on the ground that the duties involved in the satisfactory fulfilment of that office were scarcely compatible with his work in Cambridge. It caused some regret among the members of the profession in Cambridge that Paget and Humphry should, on similar grounds, though they might appear adequate to them, have declined to come forward for the presidencies of their respective London Colleges. In 1872, on the death of Dr. Bond, the unanimous feeling was gratified by the Crown appointment of him as Regius Professor of Physic. He was thus placed at the head of the School of Medicine, then fairly started on its prosperous career, to the furtherance of which his wise administration and energy and the confidence reposed in him not a little contributed. With keenly observant eye he watched over its interests, and was ever present to defend its cause. He fulfilled to the last, with his wonted care and conscientiousness, the various duties of the professorship, giving his lectures, taking part in all the examinations for M.B., and, which is now no light matter, presiding at all the exercises for M.B. and M.D., as well as presenting candidates for their degrees, and acting as chairman of the Special Board of Medicine. He received the honour of K.C.B. from the Queen, having attended both

Digitized by Google

the Prince of Wales and the late Duke of Clarence and Avondale during their residence in Cambridge; and honorary degrees were conferred on him by the Universities of Oxford, Dublin, and Edinburgh. The influenza chill seized him on Jan. 14th. He never rallied from the depressing effects of the malady, and died on the 26th, in his eighty-third year.

It is to be regretted that he published so little. "A Notice of an Unpublished Manuscript of Harvey," in 1850; the Address, which he delivered as President at the British Medical Association at Cambridge, 1864, in which he strongly advocated the claims of natural science to a larger share of the teaching and the endowments of the University and the Colleges; the Harveian Oration at the College of Physicians in 1866; and occasional contributions to current medical literature, by their excellence of style and wealth of knowledge, create the wish that his pen had been more frequently employed to the advantage of the profession, and that he had yielded to the often expressed wish that he would commit to writing the many and varied experiences of his professional and his University life. He was a frequent attendant at the meetings of the Cambridge Medical Society, and always impressed his hearers by the sagacity of his remarks and the fertility of his memory in supplying illustrations from his practice often from years long gone by. The loss of such a man, it need scarcely be said, must be long and greatly felt by many old pupils and friends both in and out of the University of Cambridge.

SIR MORELL MACKENZIE, M.D.

SIR MORELL MACKENZIE was of Scottish extraction, the branch of the family from which he sprang having their ancestral home at Scatwell, in Ross-shire. He was the eldest son of the late Mr. Stephen Mackenzie, who practised at Leytonstone, in Essex, where the subject of this notice was born in 1837. Sir M. Mackenzie's father was a man of great cultivation and knowledge, being especially skilful in the treatment of diseases of the nervous system on the borderland of insanity. His mother was a daughter of Mr. Adam Harvey of Lewes, in Sussex, a lady of considerable gifts and energy of character, which were severely taxed when her husband was thrown from his carriage, causing fracture of the skull and death, without a return of consciousness. The widow, *enceinte* at the time, was left with eight children, and with very scanty means. Morell Mackenzie was at the time at Dr. Greig's school at Walthamstow, where he received a very sound education. As a boy, whilst bright and intelligent, he displayed no extraordinary powers or force of character. The truth probably was his abilities rendered his school tasks easy, and his work excited no enthusiasm. The sudden death of his father and the altered circumstances of the family, however, called forth his latent powers. It was necessary for him to do something for a livelihood, and he obtained a clerkship in the Union Insurance Office. The work was, however, uncongenial, and he determined upon a medical career, and to accomplish this he devoted his evenings to preparation for the matriculation of the London University. It is doubtful if he would have been able to carry out his intentions but for the generous aid of his maternal aunt, Miss Harvey, who not only defrayed the expenses of his education at the London Hospital, where he passed a most distinguished career, but continued her aid after he had become qualified in 1858, and enabled him to complete his professional education by studying for a year in Paris, and for a year subsequently in Vienna, and then afforded him the means of starting in practice. In 1859, when visiting Pesth, he became acquainted with Czermak, who had just rendered practical the discovery by Garcia of an instrument for the direct examination of the larynx. Impressed with the importance of the aid to the diagnosis and treatment of diseases of the throat afforded by the laryngoscope, and rapidly acquiring dexterity in its use, Morell Mackenzie came back to England, where he was the first to introduce the instrument. On his return he was appointed resident medical officer to the London Hospital, which office he held for eighteen months, and then became its first registrar. In 1861 he took his M.B. degree with honours in three subjects, and his M.D. in the following year. In 1866 he was elected assistant physician to the London Hospital, and in 1873 became physician. He was lecturer on physiology, jointly with Dr. Hughlings Jackson, for several years during this period. It will thus be seen that his medical training was exceedingly general, that his experience of medicine in all branches exceptionally wide, and that he was interested in the scientific as well as in the practical field. During these years he had, ever since his return from the Continent, been steadily pursuing his observations on diseases of the throat, and determined to devote himself to this subject.

Morell Mackenzie commenced practice in 1862, and his success from the first was remarkable. He was a genuine believer in specialism as the means of advance in the study and treatment of disease, and took an active part in forming the various special departments at the London Hospital. His articles on specialism in the *Fortnightly Review* in 1885 were somewhat aggressive assertions of his opinions on this subject, which excited a good deal of attention. The history of the Throat Hospital has been somewhat chequered. Dissensions have more than once arisen amongst the staff, and led to its reconstruction, and some years ago the Prince of Wales withdrew his patronage from the institution. Here, however, Mackenzie did his best work; his powers of teaching and demonstration, his manipulative dexterity and skill in operating, attracted large numbers of physicians from all parts of the kingdom, and, indeed, from all parts of the world. The publication of his monograph on "Growths in the Larynx," based on 150 observed cases and reports of 100 consecutive cases in 1871, raised him to a premier position in this department of his subject. His representative position as a leading laryngologist was recognised by his being appointed president of the Section of Laryngology of the International Medical Congress held at Copenhagen in 1884, and by the fact that when the British Laryngological Society was founded in 1888 he was elected its first president.

His very extensive practice compelled him to resign his office of physician to the London Hospital in 1874, but he continued to give a summer course of lectures at the London Hospital until 1885. His practice was an extremely large and lucrative one, but was enormously increased by the number of patients from whom he would not receive, or who were not in a position to offer him, a fee. He recognised in the fullest manner the claims of his professional brethren, and placed his services unreservedly at their disposal. He was extremely fertile in resources of treatment, not only as a curative means, but as regards palliative measures where nothing else could be attempted.

Sir Morell Mackenzie was an industrious writer. He obtained the Jacksonian Prize of the Royal College of Surgeons in 1863 for an essay on "The Pathology and Treatment of Diseases of the Larynx." In 1865 he published the first edition of "The Use of the Laryngoscope," which ran through three editions. He next published a monograph on "Hoarseness, Loss of Voice, and Stridulous Breathing in relation to Nervo-Muscular Affections of the Larynx"; in 1871 appeared "Growths in the Larynx," already alluded to; in 1879. "Diphtheria: its Nature and Treatment"; in 1883, "Hay Fever," which ran through three editions; and a semi-popular work on the "Hygiene of the Vocal Organs" in 1886, which has been translated into seven languages. He wrote the articles on Diseases of the Larynx in Russell Reynolds' "System of Medicine," and in the later editions of Aitken's "Principles and Practice of Medicine" revised the chapters on the Laryngoscope and Diseases of the Larynx. He brought out alone, or with the collaboration of his colleagues, four editions of the Pharmacopœia of the Hospital for Diseases of the Throat. He contributed frequently to the Transactions of the Clinical and Pathological Societies and to the medical journals, the most important of these smaller publications being an article on the "Differential Diagnosis and Treatment of Bronchocele" in THE LANCET of 1872. His *magnum opus*, however, was his systematic work on "Diseases of the Throat and Nose," the first volume of which appeared in 1880 and the second volume in 1884. This immediately took its place as the standard work on the subject. That such an amount of literary work should have been accomplished by one of the busiest physicians of his day is in itself remarkable; but it is simply extraordinary when, in addition to the professional demands on his time, his indifferent health, caused by almost constant asthma, is taken into consideration. With respect to his writings, all reviewers are agreed in recognising his clearness, precision, and literary style. He endeavoured to deal exhaustively with whatever subject he wrote upon, and took extraordinary and scrupulous care in working up the history and bibliography of every subject, never being

Digitized by Google

satisfied until every reference had been verified. In the latter matters he often obtained the aid of successive assistants and secretaries, but no one can claim to have done more than prepare the ground for him to work upon, for not a line and not a word passed without revision and re-revision several times before it satisfied his critical judgment. He was undoubtedly possessed of great literary powers, based on a sound education, retentive memory, and unusually wide reading. Writing was to him, in a great measure, a recreation. His article on specialism, already alluded to, was characteristic of his polemical bent. He was never content with occupying a defensive position, but at once carried the war into the enemy's camp with a vigorous assault, fearless of consequences to himself.

The fact that he was called in consultation with those already in attendance on the case of His Imperial Highness the Crown Prince of Germany, the nature of the malady from which the distinguished patient suffered, and the momentous importance attaching to the opinion formed and the issue of the malady, directed public attention to him in a manner which is rarely the fortune, bad or good, of any member of the profession. For his services to his patient whilst yet Crown Prince, Her Majesty conferred the honour of knighthood upon him, and when his illustrious patient ascended the throne as the Emperor Frederick III he, in very gracious terms, bestowed on Sir Morell Mackenzie the Grand Cross and Star of the Hohenzollern Order. After the fatal termination of the Emperor's illness a lamentable controversy arose in consequence of an attack upon his conduct and skill contained in a report by Professors Gerhardt and von Bergmann, which was replied to by Sir Morell Mackenzie in a book entitled "The Fatal Illness of Frederick the Noble." It is unnecessary to again enter into the details of the case or the mode in which the controversy was carried on. All are agreed as to the difficult and delicate position in which Sir Morell Mackenzie was placed, and most would probably now like to take an indulgent view of the manner in which he conducted his case. There are, however, two points which in justice to him should be touched upon. In the first place, it has been often asserted that he, whilst recognising the cancerous nature of the disease, concealed this knowledge with the intention (laudable or otherwise) of benefiting his patient's position with regard to the contingent vacancy in the throne. The present writer had frequent opportunities of discussing this question with Sir Morell Mackenzie, who never deviated from the position he took up in his report of Feb. 12th, 1888, which was printed in THE LANCET of Feb. 18th of that year. His position he then clearly defined by pointing out that it was one of those rare instances in which the clinical symptoms were indecisive, that the microscopical examinations of Professor Virchow had shown no evidence of cancer, and that the progress of the case alone permitted its characters to be determined. The second point is as to his entering upon a controversy upon the case, and the manner in which he conducted his share in this. Whilst deeply resenting the attack made upon him, Sir Morell Mackenzie hesitated whether to reply. The opinion of his intimate friends was somewhat divided on the subject, and he asked the advice of several statesmen, who thought he ought to take action in the matter. His decision was finally determined by the opinion of the highest authorities in this country, informing him that, as the statements contained in the reports of Professor Gerhardt and von Bergmann were contained in an official State document, and were not a mere newspaper attack, he was bound to reply to them. As to the mode in which the reply was actually carried into effect, those who advised him had of course no share or responsibility. Opinions differed as to the wisdom and form of the reply. Whilst some approved of it, the great majority of medical men, including the Royal Colleges of Physicians and Surgeons, who passed condemnatory resolutions on the matter, regarded it as an improper manner of vindicating his professional character and skill, no matter how these were aspersed and whatever provocation he received. The views of THE LANCET on the matter were fully expressed at the time.

In person Sir Morell Mackenzie was of tall stature and of slender build. He had a massive forehead, deeply set eyes, somewhat prominent cheekbones, due to his Scottish blood, and a mouth expressive of great determination. His eyes and complexion were dark, and his black hair had not a silver streak at the time of his death. He had a most impressive and kindly manner, which added greatly to his attractiveness. His tastes were highly artistic, he had travelled widely, and nearly all his holidays had an educational character. At one time he visited Norway to study the leper establishments, at another taking up geology, or, again, architecture. From the nature of his profession he was brought into contact with most of the eminent and interesting personages of the day, several members of the Royal family being patients at different times. He was profusely hospitable, his circle of friends unusually wide, and greatly attached to him. He was of an affectionate nature, a loyal husband and a devoted parent. To his fatherless brothers and sisters he acted a father's part, and was most generous, not only to those who had claims upon him, but to greater numbers who had not.

Sir Morell Mackenzie was never robust. For more than thirty years he had suffered severely from asthma, which increased upon him as years advanced. This necessitated the most careful management at all times, and curtailed many enjoyments. His intimate friends are agreed that his constitutional vigour was severely taxed by the mental and physical strain which his close and anxious attendance on the Emperor Frederick entailed, and that his health was never entirely regained. He had an attack of influenza in November last, which left him extremely prostrate and more than ever a sufferer from asthma. He became much worse on Jan. 19th, and was confined to his bedroom with bronchitis and asthma. The latter was so severe that for several nights he could not go to bed. He became a little easier and again able to lie in bed, and hopes were entertained that he might recover. On Feb. 3rd, however, he had a fit of coughing and difficulty of breathing, followed by syncope, and he passed away quite painlessly and unconscious in about ten minutes. Memorial services were held at St. Thomas's, Regent-street, and St. James's, Westmoreland-street, Marylebone, on the morning of his funeral, which took place at Wargrave, where he had a country residence and spent some of his happiest hours. The memorial services were numerously attended by very representative congregations, but his funeral was very quiet and simple, in accordance with his expressed wishes. He leaves a widow and five children, one of the latter of whom has all but completed his medical education.

G. R. TATUM, F.R.C.S. ENG., M.R.C.P. LOND.

ON January 18th, 1892, passed away at Salisbury a venerable gentleman of the medical profession, George Roberts Tatum, at the advanced age of eighty-four years, after a long period of failing health. He was the brother of Thomas Tatum, who for many years was surgeon, and subsequently Consulting Surgeon, to St. George's Hospital, London, and of the Rev. Wm. Tatum, formerly rector of St. Martin's, Salisbury. His father was Thomas Tatum, a captain in the South Wilts Militia, his grandfather John Tatum, who was the first physician to the Salisbury Infirmary; and his great grandfather Thomas Tatum, M.D., of Salisbury, who died at Mere. The subject of our memoir was a man of extremely brilliant mental power and of great ability in the exercise of his profession. After studying at St. George's Hospital he obtained his L.S.A. in 1829, M.R.C.S. Eng. in 1830, and F.R.C.S. Eng. in 1843. In 1839 he went to Paris to study at the Hôtel Dieu, where he attended the lectures of the famous Dupuytren. He used to recount how well he remembered Dupuytren drinking his bowl of milk and walking off with a long loaf of bread under his arm, with a proud air. Such was the primitive fare they then used to provide for the medical lecturers. In Paris he witnessed the sacking of the Archbishop's palace, and saw the priests' robes floating down the Seine. He entered the palace with the mob, and picked up a leaf from Procopius' "Wars of the Vandals" when they were destroying the library. Mr. Tatum was house surgeon of the Salisbury General Infirmary from Nov., 1833, to March, 1841, and this institution owes much to him for its capital working organisation and local prestige. He was elected an Honorary Surgeon in 1841, and discharged the duties of that office with great ability up to 1860, when he was elected a Consulting Surgeon, which position he continued to hold up to the period of his decease. Of fine physique and presence and with intellectual powers of such a high order, for scholastic attainments and knowledge of his profession, as well as for brilliancy of wit and repartee, Mr. G. R. Tatum was locally without a superior.

JOHN BARKER MAWER, L.R.C.P.LOND., M.R.C.S.

MR. JOHN BARKER MAWER died at Bucharest on Jan. 31st, aged seventy-six. Invited by the Roumanian Government, he went out to Bucharest in 1858, where he exercised his profession up to within a few days of his decease. Mr. Mawer was for many years Physician to the Brancovani Hospital and other public institutions. He was the author (in Roumanian) of "The Bringing-up of Young Children," and contributed several articles to current medical literature. He was a correspondent of THE LANCET during the Russo-Turkish war of 1877 and 1878, and, aided by friends in England, he mainly sustained a hospital of thirty beds for Roumanian soldiers. He declined a Roumanian decoration, saying that he was sufficiently compensated when the Prince and Princess—now King and Queen—of the country visited his hospital and personally thanked him for what he had done for their wounded. He also refused a Russian decoration, but on the ground that he had done nothing for Russian soldiers. He accepted the "Medjedie" from the Sultan, as he received Turkish wounded and tended some of them even after the closing of his hospital. Courteous, gentle, and charitable, Mr. Mawer was beloved by all classes. He was buried in the Protestant Cemetery on the 2nd inst., his coffin hidden by crowns and wreaths, one of the most prominent of which bore the inscription, "From the British colony, with sincere regret and esteem."

JOHN BASSETT, M.D. ST. AND., M.R.C.S.

WE regret to record the death of Dr. John Bassett, for many years one of the professors of midwifery in Queen's College, Birmingham, which occurred on Jan. 25th at his residence at Handsworth. Dr. Bassett was in his sixty-seventh year, and had retired from active practice; indeed, his health for more than a year past had been so very unsatisfactory that his death was not unexpected. He was educated at Guy's Hospital, where he entered as a student in 1843, having among his contemporaries Norman Chevers, Cleveland, and Braxton Hicks, with whom he maintained friendships only severed by death. Coming to Birmingham in 1846, after taking the membership of the Royal College of Surgeons, he was appointed house surgeon to the old Lying-in Hospital, and after a period of useful experience in that capacity he started in practice in Hockley. When Sydenham College was founded by Dr. Bell Fletcher in connexion with the General Hospital, Dr. Bassett joined the staff as lecturer on materia medica, which post he subsequently gave up in order to assume the chair of midwifery. At the amalgamation with Queen's College he became one of the joint professors of midwifery, a position he retained till a year or two ago, when failing health compelled him to resign. He was for a long time a member of the College Council, his resignation having been received at the last annual meeting of the governors of the College. In 1879 he delivered the Ingleby Lectures, which were published in the *Birmingham Medical Review*. His other contributions to medical literature were chiefly on obstetric subjects, among which his paper on Secondary Hæmorrhage is generally regarded as a classic. Dr. Bassett was twice married, and leaves a widow and two daughters. His son, Dr. H. Thurstan Bassett, died in South Africa last September. The profession in Birmingham will long remember Dr. Bassett as a worthy and amiable colleague, a devoted teacher and an honourable and upright man, who filled for many years a very useful position in the medical school, and did his duty without any thought for himself.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AT an ordinary meeting of the Council, held on the 11th inst., the minutes of the quarterly Council on Jan. 14th were read and confirmed.

The address of condolence to Her Majesty on the occasion of the decease of his Royal Highness Prince Albert Victor was read and entered on the minutes. Also the address of condolence to their Royal Highnesses the Prince and Princess of Wales on the occasion of the decease of H.R.H. Prince Albert Victor, prepared by the President and Vice-President, and forwarded by them. A letter of the 4th instant from Sir Francis Knollys was then read, expressing, by desire of their Royal Highnesses, the Prince and Princess of Wales, their heartfelt thanks to the President, Vice-President, and Council for their warm sympathy. Letters of the 25th ult., from Mrs. John Wood and Mrs. Berkeley Hill, thanking the Council for their resolutions of condolence, were also read.

Mr. A. E. Durham was elected a Vice-President for the remaining period of the Collegiate year, in the vacancy occasioned by the death of Mr. Berkeley Hill.

It was agreed that, as recommended by the Nomination Committee, the qualification for the office of Examiner for the Fellowship or Membership be unrestricted—that it be no longer necessary that the examiner be a Member or Fellow for either examination.

Mr. H. G. Howse, being eligible, was re-elected a member of the Court of Examiners in Surgery. Mr. Marcus Beck was elected an Examiner in Surgery in the place of the late Mr. Berkeley Hill. A letter of the 27th ultimo, from Mr. Wilde, was read, reporting that the action of Steele *v.* Savory had been dismissed by Mr. Justice Romer, with costs. The shorthand notes of the trial of the action were directed to be entered in the minutes.

The Council, in pursuance of their resolution on March 4th, 1889, proceeded to the further consideration of the infraction of Section xvii. of the By-laws, and resolved again to defer the consideration thereof to the next meeting of the Council on March 10th. In reference to this subject the Council determined that the Fellows and Members concerned be informed of this resolution.

Letters were read from Dr. Liveing, reporting the proceedings of the Royal College of Physicians on matters affecting the two Colleges.

The Council elected Mr. Marcus Beck a trustee of the Jacksonian Fund, the Hunterian Fund, and Sir Charles Blicke's bequest to the library, in the place of the late Mr. John Marshall.

Mr. Bryant, the President of the College, was appointed Hunterian Orator for the year 1893.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on the 4th inst. Sir George Humphry was appointed to preside over the acts kept by candidates for the degree of Doctor of Medicine, and Dr. D. Macalister to preside over the acts kept by candidates for the degree of Bachelor of Medicine during the vacancy in the Regius Professorship. The proposal to appoint a Demonstrator to assist Professor Dewar, at a stipend of £100, and to abolish the office of assistant to the Professor, was carried by a majority of six. The following degrees have been conferred:—

Bachelors of Medicine and Bachelors of Surgery.—John Atlee, George Newstead Edmondson, Trevor Halket Evans, Lewis Gladstone Glover, St John's; Donald Harvey Attfield, Peterhouse; Harold Barr Grimsdale, Gonville and Caius; Edward Branson Wrench, Downing; William Carling, non-collegiate.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS, IRELAND.—The following gentlemen, having passed the necessary examinations under the conjoint regulations, have been admitted Licentiates of the Colleges:—

Ernest Harris Beaman, Henry Bouchier Hayes, Thomas Francis Dillon, John Joseph Michael Dowzer, John Henry Elmes, Malcolm Ferguson, Frank Williamson Foott, Edward Fitzgerald Frazer, William Cope Hamilton, Melville Keay, Herbert Buxton Ludlow, Edmund William Lynch, John Michael Mangan, Richard Moynahan, Alfred William Power, George Henry Russell, John Grant Warren, Reginald Joseph White, George Thomas Whyte, David Ernest Williams.

MEDICO-PSYCHOLOGICAL ASSOCIATION. — At the next quarterly meeting of the Association, to be held at Bethlem Hospital, London, on Feb. 18th, at 4 P.M., Dr. Ewart will read a paper on "Epileptic Colonies," and Dr. Hack Tuke will read for Dr. Jacobson, of Copenhagen, a paper entitled "Relations between Syphilis and General Paralysis." The Dissertations for the Bronze Medal and Prize must be sent to the President not later than the 30th of May, 1892. The examination for the Gaskell Prize will take place in July. Particulars may be obtained of the General Secretary.

LEPROSY IN THE TRANSVAAL.—A Reuter's telegram states that the Transvaal Government have had their attention directed to a number of lepers in Kaffir kraals to the north-east of Pretoria, and a report has come from Maritzburg that no fewer than fifty kraals at Ixapo—a division of Natal—were infected with the disease.

SMALL-POX IN MOROCCO.—Accounts from Mogador give grievous details of the extensive spread of small-pox in Morocco. Mellah appears to be the nucleus of the infection, and is described as being in a horrible condition of filth, whilst a large part of its inhabitants, chiefly on account of the ravages of the epidemic, are stated to be in great distress from the want of food and medical necessaries.

REMOVAL OF HUMAN REMAINS.—Application has been made by the rector and churchwardens of St. Helen's, Bishopsgate, to the Consistory Court of London for a faculty "to authorise the removal, on sanitary grounds, of a large number of remains of persons formerly buried" under the church, and disturbed in the work necessary for its restoration, to the consecrated burial-ground at Ilford.

AN INFECTIOUS DISEASES HOSPITAL FOR MEXBOROUGH.—At the meeting of the Mexborough Local Board on the 3rd inst. it was reported that an interview had taken place that day with the agent of Mr. Andrew Montagu, and that arrangements had been definitely made for the gift to the town of an acre of land on the western side of the cemetery for the purposes of land for an infectious diseases hospital.

MONTGOMERYSHIRE INFIRMARY.—The annual report for the past year (the twenty-fourth) shows that the work of the institution had been satisfactorily performed. There was a slight increase during the year to the number of in-patients, and the number of out patients under treatment remained about the same as in 1890. The year's subscriptions were less, attributed to several causes, and the expenditure shows an addition, accounted for by special cases requiring extra treatment.

THE RADCLIFFE INFIRMARY.—A quarterly court of the governors was held on the 27th ult. The auditors' report was adopted. The chairman entered into considerable detail on the financial condition of the infirmary, and regretted that he had to declare a very considerable deficit it was the more vexatious because the receipts had not fallen off. But overspending had come upon them, and in its most insidious form, for nearly every item in the accounts is slightly raised, with the result that the expenditure was £470 in excess of the receipts. As to the remedy, it must be economy and retrenchment. It is proposed to transfer £205 from a fund called the establishment fund to the general income of the house, and £400 from the Lancashire fund to the building account.

THE SEWERAGE OF CAMBRIDGE.—For many years the attention of the local authorities has been given to the diversion of the sewerage of the borough from the river. The corporation, as the urban sanitary authority, has just come to a final decision on the question. At a meeting held last week the committee to whom the subject had been referred recommended the acquiring of sixty-seven acres of land adjoining the Milton-road at Chesterton for the purpose of precipitating the solids, and utilising and purifying the effluent, and the coöperation of the Chesterton sanitary authority in this scheme is to be solicited. The committee's recommendations were agreed to. Instructions were given to prepare the plans for the whole scheme, and application is to be made to the central authority for sanction to borrow the estimated cost, amounting altogether to about £120,000.

ORKNEY AND ZETLAND ASSOCIATION.—At the dinner in connexion with the annual meeting of this Association, held last week in the Waterloo Hotel, Edinburgh, Sheriff Thoms, on behalf of the Fair Islanders, presented to Dr. Sturrock (Tranent) a gold chain and pendant in recognition of his having last August left some friends and gone ashore at the Fair Isle to render assistance in a critical case of sickness. In his reply Dr. Sturrock said the nearest medical man to Fair Isle was at Dunrossness, about forty miles distant, and he suggested that for the benefit of the islanders a Fair Isle woman should be sent to Edinburgh to undergo a course of training at the maternity hospital and at the surgical and medical wards of the Royal Infirmary. For this object about nine months' study and funds would be required.

DISINFECTION OF CATTLE SHIPS.—The owner of a cattle ship was fined £5 by Mr. Mead at the Thames Police Court this week for neglect to disinfect the cattle spaces, as required by the Animals Order of 1886.

THE LATE MR. T. H. BARTLEET.—Last week a meeting was held of the committee appointed to arrange for a memorial of the late Mr. T. H. Bartleet, honorary surgeon to the General Hospital, Birmingham. Mr. W. Septimus Harding presided. The chairman stated that apparently about £250 would have to be disposed of. Several suggestions were made as to the form the memorial should take. Ultimately, it was decided that a stained glass window should be placed in the chapel of the new hospital.

OPEN SPACES.—The Tottenham Local Board has decided to purchase Bruce Castle and grounds, situate at Bruce Grove, Tottenham, at a cost of £15,000, for the purposes of a recreation ground for the use of the inhabitants of Tottenham, and negotiations are in progress for acquiring other open spaces for similar purposes in other parts of the parish. The St. Luke's Vestry has undertaken to maintain the "Oval" at Windsor-terrace, City-road, as a recreation resort. Trees and seats will be provided by the Metropolitan Public Gardens Association.

ROYAL METEOROLOGICAL SOCIETY.—At the ordinary meeting of the Society, to be held at 25, Great George-street, Westminster, on the 17th inst., at 7 P.M., the following papers will be read:—"Report on the Phenological Observations for 1891," by Edward Mawley, F.R.Met.Soc; "The Untenability of an Atmospheric Hypothesis of Epidemics," by the Hon. F. A Rollo Russell, F R Met Soc.; "The Origin of Influenza Epidemics," by Henry Harries, F R. Met. Soc.; "Note on a Lightning Discharge at Thornbury, Gloucestershire, July 22nd, 1891," by Ernest H. Cook, D.Sc.

DEATHS OF CENTENARIANS.—The death is announced of Mrs. Hennings, aunt of the Rev. Gerald W. Bruce, vicar of Harwich, in her 103rd year. She was an extensive reader, and was endowed with keen perceptive powers and a remarkable memory.—Samuel Shields died near Londonderry last week at the authenticated age of 108 years.—The death has been reported to the Burnley Rural Sanitary Authority of Robert Moore, of Barrowford, near Rochdale, at the age of 101.—Mrs. Clegg died last week near Enniskillen, aged 101 years. Deceased resided for more than eighty years in the same house. She leaves forty-seven grandchildren (out of sixty) and twenty-four great-grandchildren.

ADULTERATION IN THE CITY OF LONDON.—Dr. Sedgwick Saunders, the public analyst for the City, in his report to the Commissioners of Sewers on the articles analysed last year, states that 169 analyses were made of food and drink. No improvement had been shown in the action of the public respecting the advantages to be obtained by their taking the initiative in submitting samples for analysis, and, as heretofore, the Act would have remained a dead letter in the City if he had not continued to employ the inspectors to collect samples for analysis. That peculiarity had not been confined to the City, for of 27,465 samples analysed during the year by public analysts throughout the kingdom, all but 107 samples were obtained by officers of local authorities. Ever since the passing of the first Act in 1875 there had been a steady diminution in the percentage of articles examined and found adulterated by public analysts.

FOOTBALL CASUALTIES.—On Saturday, during the match Shepley against Honley (Huddersfield and District Challenge Cup competition), played at Honley, the Shepley full back, in a scrimmage, was seriously injured. Medical assistance was at once obtained, but subsequently he was conveyed to the Huddersfield Infirmary, where it was found that his "spine was broken," and he lies in a precarious condition. On the same day a young man was admitted into the Leeds Infirmary suffering from a fractured leg, sustained while playing in a match between the second teams of Otley and Kirkstall, and during the progress of the final round of the Keighley Charity Cup competition at Lawkholme, between the Ingrow and Keighley Shamrocks, an Ingrow halfback fractured his clavicle; also on the same day a youth, aged twenty, died from "lock-jaw" following an accident received whilso playing on the previous Saturday for Caton against Morecambe Church Institute at the latter place.

AN INSANITARY PORT.—The Board of Trade has issued a notice that in consequence, as they assume, of the insanitary condition of the Port of Santos, Brazil, the British Consul there has suggested that no ships should for the present be chartered for that port.

THE SEWERAGE OF MATLOCK.—The preliminary work of carrying out a sewerage scheme is occupying the attention of the local board of Matlock, Bath. The estimated outlay is about £9000. It is proposed to carry the effluent through Crowford, and join the works belonging to that village.

FRENCH HOSPITAL AND DISPENSARY.—The twenty-fourth annual dinner in aid of the funds of this institution will take place at the Hôtel Métropole (Whitehall Rooms) on Saturday, the 20th inst., at 6.30 P.M., the French Ambassador in the chair, supported by the Lord Mayor and the Sheriffs of the City of London.

NEW SOMERSET HOSPITAL, THE CAPE.—The work of adding a new wing to this institution has been successfully completed. The wing faces Table Bay, the extension being towards Mouille Point. It is two storeys high. The ground floor is fitted up as a children's ward. The first floor is divided into twenty cubicles for the nurses. The cost of this addition is £6000.

DENBIGHSHIRE INFIRMARY.—The annual report—the eighty-fourth—shows a slight increase in the number of in-patients and a decrease of out-patients. The disbursements exceeded the year's income by a small amount. A special effort, with only partial success, had been made to obtain additional subscriptions. The result of the testimonial to the late chairman, Mr. Gold Edwards, was that he donated the amount raised towards support of a free bed, which will be called after his name.

THE CITY OF LONDON TRUSS SOCIETY. — The report for the year 1891 is satisfactory. The applicants relieved in the course of the year numbered 9584, bringing up the total assisted since the foundation of the charity in 1807 to 470,829. The year's total income from all sources amounted to £4370 4*s*, and the expenditure to £5179 6*s*. 8*d*. The Society continues to vigorously carry on its good work in the relief of sufferers of all ages from hernia in all parts of the United Kingdom.

MEDICAL NOTES IN PARLIAMENT.

The Opening of Parliament.

THE sixth session of the present Parliament began on Tuesday, the 9th inst. There are many important matters affecting the public health and the profession most closely in touch with it already set down for discussion, of various shades of interest and utility, intended to secure to the people better means of living under conditions tending to their welfare. The Queen's Speech alludes to the establishment of local government in Ireland and the improvement of national education. Among the private members' Bills already on the table of the House the questions of the hours for labour in shops, in mines, and elsewhere will be introduced by Mr. Provand, Mr. Pritchard Morgan, Sir John Lubbock, and Sir J. M'Kenna. Sanitary improvements are recommended by Mr. Stephens in his Bill to enable local authorities to deal separately with the sewage of their districts; by Lord H. Bruce, who has tabled a Bill to provide improved cottages for rural labourers; and by Mr. Knowles, the advocate for the registration of plumbers. Bills dealing with the liquor question have been presented by Mr. Conybeare, Dr. Cameron, Mr. B. Rowlands, Mr. Broadhurst, and Mr. Johnston; while Colonel Kenyon Slaney and also Mr. Quilter have put forward Bills intended to secure the purity of beer. Mr. Mather wishes to give local authorities the power of assisting the hospitals out of the rates, and the Poor-law question receives attention from Mr. Pickersgill, Mr. Cobb, and several other hon. members.

Foot-and-Mouth Disease.

In the House of Commons on Thursday, Mr. Chaplin, Minister of Agriculture, was questioned at great length as to the outbreak of foot-and-mouth disease. He explained the steps which had been taken by his Department, and assured the House that he was not without hope of preventing the escape of the disease beyond the metropolitan area.

The Influenza.

In answer to Colonel Howard Vincent and Mr. Cobb, Mr. Walter Long, who replied for Mr. Ritchie, said that the Local Government Board having been of opinion that a further investigation ought to be instituted with reference to influenza, with a view to discovering its origin and the best mode of checking its fatal prevalence, an inquiry had already been commenced, and was now being conducted by the medical department of the Board with the assistance of pathological and other experts. In reply to further questions, Mr. Long said that if anything should result from the present inquiry, or if the Board should see their way to offer any assistance to local authorities or the general public, they would do it at once and to the very best of their ability.

SAUNDERS, WM. S., M.D. U.S., L.R.C.P. Edin., M.R.C.S., has been reappointed Medical Officer of Health and Public Analyst for the City of London.

SEAR, F. M. T., M.B. C.M.[s] Edin., has been appointed Medical Officer for the Parish of Lerwick.

WHITCOMBE, PHILIP, M.R.C.S., has been reappointed Medical Officer of the Hospital at Gravesend.

WILDING, W. F. W., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer of Health, Hindley, vice Aspinall, resigned.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement.

BOARD OF WORKS FOR THE LEWISHAM DISTRICT.—Analyst. (Apply to Mr. Wright, Board of Works Offices, Catford, S.E.)

BRADFORD INFIRMARY AND DISPENSARY.—Honorary Gynæcologist.

CANCER HOSPITAL (FREE), Fulham-road, S.W.—Two Surgeons.

CENTRAL LONDON SICK ASYLUM DISTRICT.—Assistant Medical Officer and Dispenser at the Asylum, Cleveland-street. Salary £100 per annum, with board and residence.

CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, Victoria Park, E.—Assistant Physician. (Apply to the Secretary. Office, 24, Finsbury-circus, E.C.)

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.—Resident Medical Officer for two years. Salary £80 per annum, with board, lodging, and washing.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E. — House Physician. Board and lodging provided.

GENERAL HOSPITAL, Birmingham.—House Governor. Salary £300 per annum, with board and apartments.

HENLEY UNION.—Medical Officer for the Hambleden District of the Union. Salary £70 per annum and the extra remuneration provided by the Order of the Poor-law Commissioners, and 15*s.* per case for Midwifery cases. (Apply to Mr. Lloyds, Clerk to the Guardians, Henley-on-Thames.)

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton.—Assistant Physician.

HOSPITAL FOR DISEASES OF THE THROAT, Golden-square, W.—Vacancy on the Honorary Medical Staff.

HUDDERSFIELD INFIRMARY.—Senior Assistant House Surgeon. Salary £50 per annum, with board, lodging, and washing.

HUDDERSFIELD INFIRMARY.—Junior House Surgeon. Salary £40 per annum, with board, lodging, and washing.

LINCOLN ODDFELLOWS' MEDICAL INSTITUTE.—Resident Medical Officer. Salary £200, with Midwifery and Vaccination fees. House free, with allowance for coal, gas, rates, two Assistants, and Dispenser. (Apply to Mr. Coulson, 12, North-parade, Lincoln.)

LINCOLN ODDFELLOWS' MEDICAL INSTITUTE.—Doubly Qualified Assistant. Salary £120 per annum, out-door. (Apply to Mr. Coulson, 12, North-parade, Lincoln.)

LIVERPOOL DISPENSARIES.—Assistant Surgeon. Salary £80 per annum, with apartments, board, and attendance. (Apply to the Secretary, Leith Offices, 34, Moorfields, Liverpool.)

LIVERPOOL EYE AND EAR INFIRMARY.—House Surgeon: Salary £80, with residence and maintenance.

LONDON HOSPITAL, Whitechapel, E.—Assistant Surgeon.

NEWPORT AND COUNTY INFIRMARY, Newport, Mon.—House Surgeon. Salary £100 per annum, with board and residence (no stimulants provided).

NEWTON ABBOT UNION.—Medical Officer and Public Vaccinator for the Teignmouth (No. 9) District of the Union. Salary £75 per annum, which is to include all extra fees, with the exception of 10*s.* 6*d.* for each case of Midwifery attended, and the usual payment for vaccination. (Apply to the Clerk, Union Offices, Newton Abbot.)

NORTHUMBERLAND COUNTY ASYLUM, Morpeth.—Clinical Clerk. Board and residence provided.

PARISH OF LOCH GOILHEAD AND KILMORICK, N.B.—Medical Officer. Salary £70 per annum.

RAMSGATE AND ST. LAWRENCE ROYAL DISPENSARY AND SEAMAN'S INFIRMARY.—Resident Medical Officer. Salary £120 per annum (£10 allowed for substitute during annual holiday), with furnished apartments, gas, firing, and attendance.

ROTHERHAM HOSPITAL.—Resident House Surgeon. Salary £100 per annum, with board, furnished apartments, and washing, but exclusive of wine, spirits, and beer.

ROYAL HOSPITAL FOR CHILDREN AND WOMEN, Waterloo-bridge-road, S.E.—Resident Medical Officer. Salary £70 per annum, with board and apartments.

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, Albert Embankment, S.E.—The Chair of Chemistry.

TEIGNMOUTH, DAWLISH, AND NEWTON INFIRMARY, DISPENSARY, AND CONVALESCENT HOME.—House Surgeon (to act as Secretary). Salary £40, with board and lodging.

TOWER HAMLETS DISPENSARY.—Resident Medical Officer. Salary £120 per annum, furnished rooms, coals, gas, and attendance. (Apply to Secretary, Tower Hamlets Dispensary, White Horse-street, Stepney, E.)

UNIVERSITY OF GLASGOW.—Three Assistant Examiners. The annual fee to each Examiner is £30, and the term of office in each case is four years from April 1st next.

WEST BROMWICH DISTRICT HOSPITAL.—House Surgeon. Salary £80 per annum, with board, residence, and washing.

Births, Marriages, and Deaths.

BIRTHS.

BRETT.—On Feb. 7th, at Shepherd's-bush-road, W., the wife of W. G. Brett, M.R.C.S., L.R.C.P., L.S.A., of a daughter.

DAVIES.—On Feb. 3rd, at Lansdown, Stroud, Gloucestershire, the wife of Albert Barnes Davies, M.R.C.S., of a daughter.

DEACON.—On Feb. 4th, at Selhurst-road, South Norwood, the wife of Dr. Deacon, Army Medical Staff, of a son.

ROBERTSON.—On Feb. 8th, at Gonville House, Roehampton, S.W., the wife of A. Milne Robertson, M.D., of a son.

MARRIAGES.

CAVE—COOKE.—On Feb. 9th, at the Church of SS. Philip and James Oxford, Edward John Cave, *M.D.* Lond., of Crewkerne, Somerset, to Helen Cassandra, eldest daughter of the late Rev. S. H. Cooke, Vicar of Northbourne, Kent.

KEIFFENHEIM-TRUBRIDGE—CUNNINGHAM.—On Feb. 3rd, at St. Philip's, Kensington, L. W. Keiffenheim-Trubridge, M.D., M.R.C.S., L.R.C.P., of Cliveden-place, Eaton-square, S.W., to Eva Beatrice, third daughter of the late James Elliot Cunningham, Lexham-gardens, Kensington.

SHARP—HART.—On Feb. 3rd, at Christ Church, Bradford, Percy Sharp, L.R.C.P., M.R.C.S., L.S.A., of Brant Broughton, Newark-on-Trent, younger son of the late John Buckley Sharp, Esq., of Bradford, to Florence Elizabeth, youngest daughter of the late John Hart, Esq., of London.

SPITZLY—SHEDDEN.—On Dec. 21st, 1891, at the Kirk, Paramaribo, Dutch Guiana, South America, by the Rev. Dr. Zaalberg, John Henry Spitzly, M.R.C.S. Eng., L.R.C.P. Lond., Senior Surgeon of the Military and Colonial Hospital, to Janet Shaw Farquhar, daughter of the late Lewis Shedden, and niece of James Crawford, Thurmaston, near Leicester, England.

STORRS—GRAHAM.—On Feb. 10th, at St. James's, Norlands, Notting-hill, by the Rev. Townsend Storrs, father of the bridegroom, assisted by the Rev. G. Earle Stodart, senior curate, William Henry Townsend Storrs, M.R.C.S., L.R.C.P., of Macclesfield, to Isabel Marian, second daughter of the late Major H. A. Graham, 105th Madras Light Infantry, and of Mrs. Graham, of Trevallyn, Sandown, Isle of Wight.

DEATHS.

BURDER.—On Feb. 6th, at South-parade, Clifton, Bristol, suddenly George Forster Burder, M.D., F.R.C.P., F.M.S., aged 67.

CURTIS.—On Feb. 8th, at Petersfield, Collins Curtis, M.R.C.S., aged 55.

FEATHERSTONHAUGH.—On Feb. 1st, at his residence, Gateshead-on-Tyne, Henry Featherstonhaugh, M.R.C.S., aged 76.

GOOD.—On Jan. 30th, at his residence, Dorchester, John Good, M.R.C.S., aged 74.

HELE.—On Feb. 5th, at Rowley House, Aldeburgh-on-Sea, Suffolk, Nicholas Fenwick Hele, M.R.C.S. and L.S.A., aged 57.

KINGSLEY.—On Feb. 5th, at Mortimer-road, Cambridge, Dr. Geo. Henry Kingsley, aged 65.

MAWER.—On Jan. 31st, at Bucharest, John Barker Mawer, L.R.C.P.L., in his 76th year.

RAYNE.—On Jan. 21st, at Cambridge-gardens, W., W. Theodore Rayne, M.R.C.S. Eng., L.R.C.P. Lond., of influenza and pneumonia, after a very short illness.

REID.—On Feb. 2nd, at his residence, Aberdeen, William Reid, M.D., C.M. Aberd., aged 55.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editors."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

We cannot undertake to return MSS. not used.

FOREIGN BODY IN THE EAR.

To the Editors of THE LANCET.

SIRS,—R. W., aged forty-three, railway signalman, came to the Infirmary stating that when six years of age, something got into his left ear, but that as no ill effects ensued, his parents had nothing done. About six months ago he began to hear noises in the head, with buzzing on the left side. These got worse and he found himself getting deaf. He came to the infirmary, and on examination I detected a foreign body. After carefully syringing the ear for some time a large stone, covered with cerumen, escaped. The drum appeared quite normal, and the patient now hears quite well and is free from noises in the head. This stone, a drawing of which I send, exact size, must have been in the external auditory canal without inconvenience or doing harm for about thirty-seven years. The reason why he experienced the noises &c. during the last six months was, I think, on account of the wax accumulating sufficiently to completely block up the canal.

I am, Sirs, yours faithfully,

FRED. A. A. SMITH, M.D.,
Hon. Surgeon, Cheltenham Eye, Ear, and Throat Infirmary.

February, 1892.

G. P.—It would be well for the parties in the dispute to meet and endeavour to come to an understanding. There would seem, according to the statement of our correspondent, to be no reason why the matter should not be amicably settled.

Mr. A. T. Spence is referred to a general notice given above.

C.—Yes, in an early number.

CONDENSED MILK.

To the Editors of THE LANCET.

SIRS,—The very large quantity of condensed milk which is used by all classes for feeding young infants makes it important that the report in *The Times* of Feb. 6th on the quality of much of the condensed milk that is now being sold, particularly to the poorer classes, should not pass unnoticed. By the use of the "separater" it is possible to reduce the quantity of cream from its normal standard in cows' milk of about 3 per cent. to ·03 per cent.—that is, from 3 per cent. to 3 per 10,000. If the quantity of cream be estimated by volume, it is found to amount to about 10 per cent.—that is to say, in ten ounces of milk we shall have one ounce of cream. Therefore, on this calculation, an infant taking thirty ounces of milk a day—that is, a pint and a half—will receive fifteen drops of cream, instead of three ounces, the quantity for human milk (a pint and a half). Now, although it is generally found necessary to dilute cow's milk with an equal quantity of water for young infants, this, of course, is done chiefly to reduce the proportion of casein, which is so much greater in the milk of the cow than in that of the woman. Seeing that human milk contains as much cream as that of the cow, it does not seem wise to remove or reduce the proportion of cream. How far it is proper to remove it almost entirely, as is done in some of the condensed milks, need not be discussed. This point is deserving of attention. By the old-fashioned mode of skimming it was not possible to extract the cream nearly so completely as is done by the separater, and thus skimmed milk is a very different thing from separated milk. To sell one for the other would probably be considered by a jury a fraudulent imposition. At least, let us hope so.

I am, Sirs, yours faithfully,

London, Feb. 10th, 1892. ROBERT LEE, M.D.

Mr. Edward Shaw.—We are not aware of any separate monograph. Our correspondent will find ample information in Reynolds' System of Medicine, vol. v., and in Pepper's System of Medicine, vol. iii.

Common Sense is thanked for his communication. Mistakes of the kind are inevitable where information is drawn from various sources.

Inquirens.—Our reply must be in the negative.

AFRICAN FEVER.

To the Editors of THE LANCET.

SIRS,—With reference to your note regarding African fever, I may say that I should be very glad to have any communication from Africa or elsewhere. I have had during the previous few months various samples of blood from the West Coast of Africa, and an examination of them goes to prove that Laveran's observations with regard to malaria are correct. I have recently published my opinion with regard to the black-water fever, and therefore do not need to refer to it again; but, as far as my experience goes, it is only a form of malarial fever. The difficulty, I apprehend, with these medical men is that they go out to the tropics without having had any instruction with regard to the climatology and the various differences which disease takes in the tropics. For the last few years I have been trying to give men going to tropical regions information about these subjects, and I shall always be glad to do so in the future.—I am, Sirs, yours faithfully,

Edinburgh, Feb. 9th, 1892. ROBERT W. FELKIN, M.D.

To the Editors of THE LANCET.

SIRS,—I have read with much interest the letter of Dr. Harford-Battersby in your issue of the 30th ult., in which he mentions the so-called black-water fever of West Africa. From my experience of this form of malarial fever the appearance of the pigmented urine is merely a symptom of an unusually acute attack of ordinary remittent fever. I have never known true hæmaturia to occur in the course of a malarial fever: red corpuscles being very rarely found in the urine under the microscope, but hæmatin crystals are frequent. May not the appearance of this blood pigment in the urine be nature's method of eliminating it from the system in which it is set free by the malarial poison? I have noticed that in the few cases I have seen there was less discolouration of the skin after the fever abated in those who passed "black water," than in those who did not, and I believe that this discolouration is due, not to jaundice, as is commonly taught, but to the presence of free hæmatin in the blood. I believe, too, that the fatality of this form of fever is increased by the dread in which it is held. I should be glad to receive any information on this subject from any of your readers.—I am, Sirs, yours faithfully,

H. ATHILL CRUTTWELL, L.R.C.S., L.R.C.P.Edin.
(Late Medical Staff, Niger Territories.)

Kensington-park-road, Feb. 10th, 1891.

THE BRUSSELS GYNECOLOGICAL AND OBSTETRICAL CONGRESS.

To the Editors of THE LANCET.

SIRS,—I am authorised by Dr. Jacobs, General Secretary to the Congress, to state that the following gentlemen have been elected honorary presidents:—Drs. Priestley, Playfair, Watt Black, Elder, Galabin, Gervis, J. Williams, Bantock, Champneys, White, and Herbert Spencer; and Mr. Lawson Tait and Mr. J. Knowsley Thornton.

I remain, Sirs, yours truly,

ALBAN DORAN,
English Secretary to the Congress.

Granville-place, W., Feb. 9th, 1892.

POOR LAW MEDICAL OFFICERS ABROAD.

THE Irish dispensary doctors are not the only medical officers appointed to attend on the poor who are bestirring themselves to get their grievances redressed. The Spanish "parish doctors" have for some time past been discussing their grievances in the medical press, and have also lately held a congress for the better ventilation of their wrongs, which seem to be chiefly traceable to the parsimony and oppressive behaviour of municipal and parochial boards. The Italian parochial medical officers have also a serious but somewhat strange cause of complaint against the parochial authorities, which they are about to hold a congress at Milan for the purpose of discussing. According to a law passed some three or four years ago a medical officer, after three years' satisfactory tenure of a post, is entitled to have his appointment confirmed, after which he cannot be discharged by the local authorities. This security of tenure, however, does not please the local boards. The consequence is that they are evincing a disposition to terminate the engagements while they can do so—that is, before the three years have expired. Against these vexatious tactics appeals are constantly being made by the medical officers receiving their *congé*, first to the provincial medical council, then to the prefect, and finally to the Minister of the Interior, the results being apparently very uncertain and unsatisfactory.

Cyclops.—We think it would probably be held that (1) an unqualified assistant is not liable to any prosecution or penalty for vaccinating children.—2. The certificate states that the child has been vaccinated "by me"; and a practitioner who signs such certificate appears to be technically guilty of an offence under 30 & 31 Vict., cap. 84, Section 30. But if these words be omitted, the certificate could hardly be held to be a false one.

Medicus will see in another column of our present issue an article which deals with the subject of his communication.

Syntax should communicate with the Chairman of the Prisons Board, Sir E. F. Du Cane, Home Office, Whitehall.

Censure.—A solicitor should be consulted on the matter.

SAMARITAN HOSPITAL FOR WOMEN AND CHILDREN, BELFAST.

To the Editors of THE LANCET.

SIRS,—The paragraph from your Irish correspondent in THE LANCET of Feb. 6th in reference to the annual meeting of the above hospital is very complete and very fair. Permit me to add, however, that the bequest of £1000 by the late Miss Charters will, according to custom, be added to the endowment fund, and only the interest be used as income. The committee have always made it a rule to keep the expenditure within the income; so there is always a balance in hand. If larger hospitals would do the same, there would be less crying out for want of funds. Unfortunately, the managers of many hospitals are not large subscribers to the funds. The committee of the Samaritan Hospital are all subscribers, and everything is done in a business-like manner.—I am, Sirs, yours faithfully,

W. K. MCMORDIE, M.D.,
Surgeon to the Hospital, and Member of the Committee.

Belfast, Feb. 6th, 1892.

THE CASE OF EXCISION OF THE ILEO-CÆCAL VALVE AT ST. THOMAS'S.

To the Editors of THE LANCET.

SIRS,—I would wish to make the following additions to the case of resection of intestine reported in the "Mirror" of your issue of Feb. 6th. The operation for restoring the continuity of the bowel, after removal of the growth by Mr. Sydney Jones, was performed by Sir William MacCormac. The merit of the diagnosis of the case is due to Dr. Bristowe, under whose care the patient was at first.

I am, Sirs, yours faithfully,

Lambeth Palace-road, Feb. 8th, 1892. H. BETHAM ROBINSON.

*** With respect to the case referred to above, we understand that Mr. Sydney Jones would have performed the second stage of the operation had he not been prevented from doing so by the expiration of his term of office as surgeon to the hospital.—ED. L.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Post-graduate Lecture
ON SOME
GENERAL PRINCIPLES OF THE DIAGNOSIS OF DISEASES OF THE NERVOUS SYSTEM.

Delivered at the National Hospital for the Paralysed and Epileptic.

BY W. R. GOWERS, M.D., F.R.S.,
CONSULTING PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL; PHYSICIAN TO THE NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.

GENTLEMEN,—If we look back over the progress of medical science, three epochs of discovery stand out in special salience, contrasting, in the steepness of the rise in knowledge they present, with the more gradual progress of other branches and of the same subjects at other times. These are, first, the revolution in the conception of diseases of the heart and circulation which Harvey's great discovery entailed; secondly, the penetrating extension of knowledge of all the thoracic diseases which was effected by the invention of the methods of auscultation and percussion, and the discoveries which followed that invention; and, thirdly, the enormous advance in our knowledge of the nervous system and its diseases which the last quarter of a century has witnessed. This has been largely due to the development of microscopical research, in some degree to the progress of experiment, but very much to the extraordinary increase in the capacity for investigation which the general progress of science has produced, and to the fertile field presented by these diseases for the exercise of that faculty. The results of the application of the chemical and microscopical investigation to the urine and the transforming revelations made through the invention of the ophthalmoscope and the laryngoscope, are hardly less remarkable, but their range is more limited than those of the progress effected during the three great epochs in discovery that I have mentioned. The last of these concerns us in a special manner, because it has taken place in our own time and is still in active progress. It is to certain consequences of it that I desire to direct your attention to-day—consequences that are of the utmost importance to the practitioner in his daily work. How great, how wide and profound, has been the change that our knowledge of diseases of the nervous system has undergone cannot, indeed, be realised by all members of our profession. A large number of those who studied before the change took place have been unable to follow the new development of knowledge,—the successive stages of which have followed each other with a rapidity almost bewildering, and the difficulty has been enhanced by the freedom with which investigators have revelled in a novel nomenclature, embracing alike the new and the old, in part essential, but in still larger measure superfluous. The exigencies of practice, with its increasing demand on the time and energy of the practitioner, and its unceasing echo of the cry (shall I say of a colleague's daughter?) "Give, give!" has made it often impossible for him to attempt, or, attempting, to continue, to follow the successive discoveries. Without a knowledge of their scientific features he has generally found it impracticable to use them, and so he has either rested content with that which he learned of old, or has gained a fragmentary knowledge that has served only to mislead him. Those, on the other hand, who have learned the subject as we have it now, cannot realise the change, for they have but one of the terms needed for the comparison; while the large number of practitioners who studied medicine during the period in which the change was taking place, learned a little of the new and a good deal of the old, and acquired a mixture containing many incompatibles, with the common consequence that may be described in terms of metaphor, not inexact, as "mental turbidity."

To clear your minds and get rid, as far as may be, of all that prevents a clear vision of disease, to learn how most usefully to see disease through the clearer media, and, above all, to see it in such a way as shall enable you to treat it with such advantage as is attainable—these, I conceive, are the objects that bring together here the members of this post-graduate course. But I am not sure that the students of to-day, or at least many of them, who have acquired the latest and fullest knowledge of these diseases, have learned, in equal measure, how to use their knowledge, or are free from the need of that training in method which the practitioner feels so keenly. The reason for this, or at least the conditions that make it probable, you will perceive when I tell you the nature of the difficulty that is experienced and the character of the need that is felt.

Let me, however, first give you an illustration of the change that has come over our knowledge of diseases of the nervous system during the last quarter of a century. I remember, twenty-five years ago, listening to a lecture on "chronic spinal meningitis," given by one of the most competent teachers of the day, which presented the latest and clearest opinions on the subject. The malady, as described in that lecture, had no existence. In the case on which it was given, the membranes of the spinal cord were certainly in a perfectly normal state. The symptoms then thought to prove the existence of chronic meningitis are now known to depend solely upon changes within the spinal cord itself. The pathology had been inferred from analogy, but the new means of investigation we have since obtained, coupled with the more extensive and precise observation which I have mentioned as so salient a feature of recent progress, have proved that the analogy was false and the malady quite different from that which was supposed to exist. The symptoms which were then ascribed to chronic meningitis are, indeed, now known to manifest more than one distinguishable disease. But the chief source of practical difficulty is not the mere correction of erroneous inference, and the displacement of the work of fancy by ascertained fact; it depends on the vast increase in our knowledge of the anatomy and physiology of the nervous system and on the application of this to disease; it depends, further, on the revelation, effected by microscopical research, of the extent and variety of degenerative processes in all parts of the nervous system. It depends, lastly, on our ever-widening perception of so-called "functional," really nutritional, diseases for which no anatomical cause has yet been discovered, which have been distinguished or recognised by means of (1) the increased exactness of observation, (2) the aid received through the differentiation of processes formerly confused with these, but now known to depend on structural change, and (3) in consequence of the special indications afforded by the discoveries now being made of the vast range of influence of toxic agents on the nervous system. Can we wonder, then, that our knowledge has been changed, even to the point of transformation, and that those familiar only with the old should be almost lost in the mazes of the new? The practical effect of these changes is to render the customary methods of diagnosis wholly inapplicable to a large proportion of cases of disease of the nervous system, to render it useless, or more than useless in the case of a large number of the nutritional affections that are called "functional," and of the structural maladies that are called "degenerative," as well as many of the maladies that depend on the visible and conspicuous changes that are called "organic."

The student has to acquire his knowledge of all diseases by the method of "types," and the same method is employed in the practical diagnosis of most other maladies. Indeed, in the case of many, no other system of recognising the nature of a case could be employed than that of observing the correspondence of the symptoms, in character and course, with those of a certain form which is known by a special name. But when we turn to the diseases of the nervous system that I have indicated, we meet with a series of maladies the variety of which is almost infinite. When we consider the various structures comprised in the "nervous system," their diversity of function, the extremely numerous combinations of structure and function that may be deranged at the same time, all mutually acting and reacting to produce the manifestation of disorder; when we consider further the variety of nutritional and degenerative processes to which these structures are liable, and also the degree and extent to which they are influenced by toxic blood states—agencies that we are only beginning to perceive in their nature and diversity,—we can readily understand that it not only may be, but that it must be, true that the diseases we meet with are so numerous and so diverse as entirely to

baffle an attempt to range them under definite types, that can be designated by definite names. But in the series they form, there are here and there aggregations, as it were, in which the morbid process corresponds, at least in its chief features, varying only in minor points. These we treat as types, and call by names, and by them the student learns the general features of the classes of disease in which they occur; but they seldom stand alone or are marked off by any well-defined boundary. Intermediate cases connect adjacent groups—cases that combine the features of two or several, or present some characteristics of one and some of another, and very often symptoms that cannot be recognised as pertaining to any recognised type. Of these forms, numerous as they are, the student for the most part remains ignorant. He has enough to do to become acquainted with the more familiar groups, and the method by which he learns the features of these cannot take in the intermediate varieties. When he proceeds to practical work he soon finds himself confronted by cases the like of which he has never heard of, and which he cannot find described in any text-book of these diseases. If he attempts to identify them, to bring them under some recognised type, and to give them some definite name, he is at once and completely baffled. He is baffled of necessity, for the cases belong to no type, and no name can be given to them that does not involve more error than truth. It cannot be otherwise, for to constitute types and assign designations that would include even the chief of these varieties would be to multiply both types and names beyond the capacity of the human mind to learn, or its power to retain. In the case of these diseases, therefore—diseases that are so frequent as to make up at least half the cases of affections of the nervous system which the practitioner has to treat,—the method by which he has acquired his knowledge, and by which he is able to deal successfully with almost all other classes of disease, fails him entirely; and yet in most instances he has nothing to put in its place. "The old order changes"; but it is "giving place to new" with a slowness which, at the present day, is a source of perplexity and difficulty widely felt, and constitutes a really serious obstacle to the practitioner's work. That it is so—that I am not exaggerating the facts—will be, I am convinced, confirmed by most of those who bring to their work the earnest and thorough spirit which strives to understand the cases that have to be treated, which strives after light, and is not content merely to deal, in darkness, random strokes.

What, then, is the remedy? What new method of diagnosis can be adopted? Happily, there is a means of meeting the difficulty, before which its formidable features will vanish, and the ever-growing accumulation of facts, the ever-increasing variety of definite morbid states of the nervous system, however numerous, however complex, however unfamiliar, may be dealt with as readily, as surely, as the diseases of any other class, or as the affections of the nervous system that do correspond to types, and may be recognised by such correspondence. Indeed, I had almost said that the method I am about to recommend enables you to deal with these diseases more readily and more surely than the other. At least, it has the advantage of placing the practitioner at once in the position needed for the adequate and wise treatment of the malady so far as such treatment is within our reach.

The method you should adopt is this: Whenever you find yourself in the presence of a case that is not at once and completely familiar to you in all its details, forget for the time all your types and all your names. Deal with the case as one that has never been seen before, and work it out as a new problem, *sui generis*, to be investigated as such. Observe each symptom carefully, and consider its significance. Then put the several symptoms together, and consider the meaning of their combination, especially whether there is any one part of the nervous system at which disease might cause them all. Lastly, consider the way they came on, as indicating the nature of the lesion, comparing this with the evidence of their seat, and remembering also that their character may in itself tell you something of their probable nature. When described in the abstract, this may seem a lengthy process. It may even seem a formidable process. As a rule, it is neither. The common symptoms, even those presented by uncommon cases, are not numerous, so far as concerns their general character and actual nature. The question of localisation is only an application of the common physiology of the nervous system, of the facts that should be familiar to every student, and can be re-learned, if necessary, with ease, by every practitioner. All the knowledge needed for this method is that which every student gains, or ought to gain, in the course of his studies; it is only the mode of using the knowledge that is new and has to be acquired. But the student should remember the great importance of "keeping up" his physiology and anatomy of the nervous system, or at least those parts of it which are needed in practical work. There is no department of medicine that consists more largely of applied physiology and applied anatomy than these diseases. For this reason they should engage the attention of the student early in his hospital work, instead of, as is often the case, being relegated to a late period on account of their supposed difficulty—a period when his science has got "rusty," or has slowly vanished, until even its nomenclature awakens a mere echo from bare walls. As a matter of fact, much of the student's hindrance is due to this postponement. The application of his knowledge should be made to retain it.

But for the successful use of this method it is essential that the knowledge, though neither extensive nor profound, should be firmly grasped and boldly used. Herein lies the chief practical difficulty. Timidity is almost a greater hindrance to diagnosis than is ignorance. You must feel sure of the meaning of symptoms, you must weigh the evidence with care, and then you may and must feel confident that your conclusion is trustworthy. This confidence and boldness can only be acquired by familiarity with the process, by observing its use by others, and afterwards repeating it for yourselves, thus becoming so familiar with the language of disease that you can read it with ease, can see at once the meaning of its words, and perceive with readiness the significance of its sentences. It is by affording an opportunity for this that the attendance on the practice, especially the out-patient practice, of special hospitals, is of peculiar value to the student, whether pre-graduate or post-graduate. A series of cases of the same class pass before him, in each of which he can observe the character of the symptoms and the process of diagnosis, and thus he gains, in a short time, a familiarity with the features of disease, and a quickness in perceiving their meaning, that he could not obtain in a long period of work at a general hospital, where such cases are few and far between, and the lesson of one is more than half forgotten before another instance comes before him.

In all this method of dealing with unfamiliar maladies there is nothing that is not within easy reach of the average student or practitioner. If any difficulty is felt, it is only, as in so many subjects, the first step that costs a conscious effort. Once learned, the method becomes more easy with each repetition, and is acquired the more speedily if repeated under slightly varying conditions. Soon, its steps cease to be consciously felt, and in a short time even a student, who has been fairly grounded in the elementary knowledge, becomes able to use the method with precision, and succeeds, in four-fifths of the cases that would otherwise baffle him, in arriving at a diagnosis in which a physician, whose attention has been given for years chiefly to these diseases, can find little or nothing to change. Note, moreover, that the method indicated is that which the most experienced physician has himself to adopt in the case of a large proportion of the cases that come or are sent to him. So infinitely various are the morbid states of the nervous system, so diverse their manifestations, that a very large number of the cases seen are practically new, even to a man of the largest experience, and if asked he has to confess that he has not seen before any case precisely similar to, and often not one even approximately resembling, that before him. Yet, by employing this method, he is able to arrive without difficulty at a diagnosis as sure as when the malady is of a common type. The only difference between his work and that of the student is that the latter has to adopt the method, with scrupulous care, in a larger proportion of the cases that he sees. He has to deal with a larger number as essentially new problems, to be worked out *de novo*. If he does this, as I have said, his errors will be few and rare, and only a small proportion of the cases will baffle his efforts. But never forget the essentials of the proceeding. Remember that you must for the time discard entirely your types and names. When you have made your diagnosis in the manner I have described, then, and then only, may you

Digitized by Google

consider how far the case corresponds to a type and can be called by a familiar or unfamiliar name.

The last point suggests a common difficulty. The desire for a name is strangely strong in the case of the majority of patients. Unless their disease is designated, they go away unhappy, discontented, distrusting. "But you have not told me what is the matter with me" is their parting plaint. What are you to do? In a very large number of cases no recognised name can be given to the disease that does not involve more error than truth. A few patients are sufficiently sensible to endure the knowledge of the fact and be content with it. In the case of most, the best plan is to give them a descriptive designation, and to write it down, that there may be no mistake, or it will come back to you some day in altogether altered form, so changed that you do not recognise your own production. The descriptive designation need not necessarily be short, although often it can be, and is then satisfies as much, provided the words are unintelligible. "Cephalic dysæsthesiæ" makes many a sufferer content. "Paroxysmal neuralgic pains, due to damage to the third and fourth posterior spinal roots, owing to a stationary lesion of the intervertebral articulations," delighted one good woman whom I lately saw, and who earnestly desired to know what was the matter with her, no doctor, she said, having as yet informed her. But always adhere strictly to fact in these descriptions, and avoid words that are apt to mislead because used in various ways. If you use the term "sclerosis," for instance, the chances are that the patient will look up the word in some medical dictionary, will identify his malady with insular sclerosis, read, forecast his future, and become utterly miserable.

To sum up in a few words the necessary change. Discard in the first instance all attempts to identify or to name, and try instead to read the malady, tracing the symptoms to the seat of their cause, and discerning the nature of the morbid process by their character and course. The method has the great practical advantage of taking you at once to the elements that should guide your treatment, and of enabling you to treat wisely a case the like of which you have never heard of, and a name for which you may not know. Mind, I do not say that you need adopt this process in every case of disease of the nervous system that comes before you. There are many that do belong to familiar types, cases that are characteristic and perceived at once to be such—cases of common chorea, for instance, of idiopathic epilepsy, many forms of hemiplegia, and the like. But the method is needed in all unfamiliar maladies, and in all cases even of familiar aspect that present some unusual feature; often, such a feature, in the end, is found to indicate that the case merely resembles superficially that to which it seemed to correspond, and is really quite different in nature. How real and how extensive is the need for the change in method I have described can only be realised by those who have to correct the mistakes or supplement the deficiencies of those who first attempt to make a diagnosis of such cases as I have indicated. In many cases a practitioner candidly confesses his inability. I often receive a letter saying, "I cannot make out what is the nature of the disease; I have seen nothing like it before, and I cannot find its features described in any text-book." Yet the case, as a rule, readily yields to the application of the method I have described. More often, however, the practitioner has endeavoured to make a diagnosis by the familiar system of types, and has, as it were, forced the case into the receptacle that seemed to correspond most nearly to it, but into which it did not really fit, and has given it a corresponding name, more or less erroneous, and often ludicrously wrong. I abstain from giving you instances; the statement of the fact will suffice, and examples are so numerous that some one would probably find that the cap fitted him with unpleasing precision.

I should like to have given you some instances of the working of this method, but for this there is not time. You will find it easy and more useful to work out such examples for yourselves, beginning with familiar diseases, but treating them, for the occasion, as unfamiliar. I hope, however, shortly to give you in another lecture a series of examples of its use, although not nominally such, by describing and analysing some of the more important diagnostic signs, or "diagnostic guide-posts" as we may call them. Familiarity with these is of extreme value, and most of them will afford illustrations of the use of the method I have just described.

Clinical Lectures
ON
STRICTURE OF THE ŒSOPHAGUS,
WITH FOURTEEN ILLUSTRATIVE CASES, IN FOUR OF WHICH GASTROSTOMY WAS SUCCESSFULLY PERFORMED.

BY DAVID NEWMAN, M.D.,
SURGEON TO THE DEPARTMENT FOR DISEASES OF THE THROAT AND NOSE AT THE ROYAL INFIRMARY, AND ASSISTANT SURGEON TO THE WESTERN INFIRMARY, GLASGOW; PRESIDENT OF THE GLASGOW PATHOLOGICAL AND CLINICAL SOCIETY.

LECTURE III. (*Concluded.*)

I HAVE now discussed at sufficient length the intra-œsophageal operations for the relief of stenosis, and we may now pass on to consider the other methods either of relieving the stricture or of introducing food through an artificial opening.

Œsophagostomy, or the establishment of a fistulous opening in the neck for the relief of stenosis of the gullet, was first suggested in 1615, but on account of the obstacles to performing such an operation without anæsthetics, and probably also from the erroneous belief in the dangers and difficulties in its execution, surgeons were deterred from adopting it until 1738, when it was for the first time successfully performed. The whole subject has been very fully discussed in a valuable and exhaustive monograph by Terrier,[1] which I would strongly recommend you to read. While twenty years ago, or even at a more recent date, the operation was looked upon as very dangerous, more recent experience has demonstrated that it is not only quite a legitimate surgical procedure, but, under favourable circumstances, one of very high value when resorted to for the removal of foreign bodies only. I cannot here refer to those instances in which œsophagostomy has been employed for the removal of foreign bodies further than to show you that a consideration of the statistics up to the present day gives most encouraging results. Dr. T. M. Markoe, in the *New York Medical Journal* of May 1st, 1886, says, referring to cases in which œsophagotomy was performed for the removal of foreign bodies: "I am indebted to my friend Dr. S. W. Gross of Philadelphia for the following statement, which he very kindly gleaned for me from his abundant statistical resources. The whole of the persons operated upon up to date (1886) is eighty-two. Of these cases, sixty-three were successful, and nineteen followed by death; of the eighty-two cases, the foreign body was found and removed in seventy-four, and of these fifty-seven recovered and seventeen died. The foreign body was not found in seven cases, and in one case it was found, but slipped into the stomach and passed per anum. ..... Of the sixteen fatal cases of œsophagotomy, eight are stated to have died of abscess provoked by the lodgment of the foreign body, two from exhaustion, two from septicæmia, one (of pneumonia, and the rest not clearly stated."

The operation of œsophagostomy is only suitable when the disease is situated at and limited to the upper few inches of the gullet, and where there is evidence that firm adhesions have not formed between the œsophagus and neighbouring parts. In some cases the stenosis is so complete that it is very difficult to introduce the point of a knife into the lumen of the tube; and, moreover, although it is easy to determine the upper limits of the stricture, it is seldom possible to make out where the lower margin is. Mr. H. A. Reeves, in the Transactions of the Clinical Society of London, vol. xv., p. 32, gives the following as his conclusions:—"1. That internal œsophagotomy being out of the question, and the stage for gradual dilatation being passed, and in consequence of the great mortality of gastrostomy, and also because of the more frequent occurrence of malignant stricture in the upper portion of the tube, œsophagostomy is by far the preferable operation. 2. That even in cases where the stricture is as low down as the manu-

[1] De l'Œsophagotomie Externe, Thèse de Paris, 1870.

Digitized by Google

brium sterni (its depth being rarely very great), œsophagostomy is indicated as a preliminary or exploratory operation; and if it be found that the little finger or sound cannot be got through the narrowing, gastrostomy may be performed. 3. That if it result that the opening in the œsophagus has been made below the stricture (as in most cases would be desired), the operation can be completed by stitching the mucous membrane to the wound edges, and the stricture may, if thought proper, be dilated through the opening at the time of operation or subsequently. 4. That if diseased œsophagus be reached, and no opening into it can be made through healthy walls, then it may be carefully perforated, either by the finger or the thermo-cautery. 5. Œsophagotomy has been many times done, and œsophagostomy several, and never have these operations caused any grave local or general symptoms, or, as operations, led to the death of the patient, whereas gastrostomy has proved most fatal. 6. The operation should be done on the left side of the neck, and a sound should, if possible, be passed, that of Vacca Berlinghieri being the best. The skin incision should be rather nearer the mid-line than that for ligature of the common carotid, and should extend from half an inch above the episternal notch to the level of the upper border of the thyroid cartilage. The surgeon should stand on the left of the patient, looking obliquely down and across his or her body. A tube with a funnel-shaped end should be passed and tied in place, and nourishment administered as soon as the tendency to vomit caused by the anæsthetic has passed off. It is necessary to make the opening in the œsophageal walls with a sharpish stab, to prevent the loose mucous membrane being pushed before the knife. The edges of the wound may be stitched up, and care taken that no food gets into it. 7. The operation should be undertaken before the patient's strength is much exhausted, and even before obstruction is complete, because, frequently, attempts to swallow produce spasmodic suffocative dyspnœa, as in the first case related. 8. In severe cases of simple fibrous or syphilitic stricture in the nuchal or upper thoracic portion of the tube, œsophagostomy is indicated, as then the operation might be made curative as well as palliative. 9. Internal œsophagotomy must be limited to an extremely small percentage of cases, and some think it not justifiable, and excision of the diseased part of the œsophagus is yet in its merest infancy, so that œsophagostomy is the best resource left us, and the operation, if performed with care, is not very difficult."

The question of what operation should be employed is so important that I will not hesitate to discuss in detail the points raised by Mr. Reeves. From his own showing œsophagostomy is only suitable for those cases in which the disease occupies the upper part of the canal, and he says that this portion of the gullet is most frequently attacked, but unfortunately he does not state very clearly what he means by the upper portion of the tube. From what has been said in a former lecture, you will observe that I have come to the conclusion that the most common spot to find the primary tumour is immediately behind the cricoid cartilage; so that, if the patient presents himself to the surgeon sufficiently early, a successful œsophagostomy may be performed. But, as a rule, the aid of the surgeon is not asked until the disease has extended beyond the limits just mentioned. When the patient is seen at an early stage and the healthy œsophagus can be exposed below the site of the disease, so that the healthy mucous membrane can be stitched to the skin, then I think œsophagostomy may be employed. But to make an incision in the neck, and through the tumour into the lumen of the canal, seems to me unjustifiable when gastrostomy may be performed. You will therefore perceive that the operation is very limited in its application. Of the cases which I have brought before you, in not one of them could it have been performed in the hope of having a satisfactory result. If, for example, in the cases of Mrs. C—— (Case 4) and W. F—— (Case 3), I had opened the œsophagus in the neck, the probability is that within a few weeks I would have had to contend with a large fungating mass protruding through the fistula, whereas by performing gastrostomy the wound is far removed from the site of the tumour. Before concluding the discussion of this subject it would be advisable to refer to statistics, and in doing so I may say briefly: observe that out of twenty-nine cases operated on by œsophagostomy ten lived over one month, while the great majority of the remaining nineteen died within a week of the operation. The most successful case recorded is one operated upon by Hadlich[2] in 1880; the patient was sixty years of age, and was suffering from severe dyspnœa, the cause of which is not stated, and no necropsy was permitted, when the patient died thirteen months after the operation. With such unfavourable results it is not surprising that œsophagostomy has fallen into disuse.

In performing œsophagostomy the patient should be placed upon his back with the head and shoulders slightly raised, and, an anæsthetic having been administered, the face should be turned to the right. The surgeon, standing to the left of the patient, should then make an incision through the skin and subcutaneous tissue three or four inches long, along the inner border of the left sterno-mastoid muscle. The superficial fascia, the platysma myoides, and the deep fascia should then be divided, the inner edge of the sterno-mastoid exposed, and the muscle drawn outwards and upwards by a broad retractor, so that the carotid sheath is exposed to view and held to one side by an assistant. The connective tissue having been separated with the finger or a blunt instrument, care being taken not to injure the superior or inferior thyroid arteries or the recurrent laryngeal nerve, the left lobe of the thyroid gland and the trachea are exposed. These structures should be drawn forwards and to the right by a second assistant, when the lower part of the pharynx and œsophagus will be seen lying behind. In cases for which œsophagostomy is required, a tube cannot be introduced through the mouth, so that the operator is not assisted, as in œsophagotomy, by its presence in the canal. When the gullet is found, an incision should be made in its wall. If the operation be undertaken for malignant disease, the lower down the opening is made the better, and if possible the margins of the mucous membrane should be carefully stitched to the edges of the cutaneous wound. In cases of cicatricial stenosis the incision should be made immediately below the stricture. A soft flexible tube should be introduced, and kept in position with sticking plaster, while a drainage-tube may be passed through the lowermost limits of the wound and the edges united by sutures. The after-treatment must be carried out with great caution, special care being required in the introduction of the feeding-tube. A good plan is to have a soft curved elastic tube, from 4 in. to 5 in. long and of the size of a No. 9 bougie, with a shield the same as a tracheotomy tube, fixed in permanently, and through which, when the patient is fed, a soft inner tube of smaller size is passed into the œsophagus. This avoids the danger of lacerating the wall of the œsophagus or of adjacent tissues.

You may reasonably ask me, Is it not possible, in cases where the carcinomatous growth is situated high up, as in those of W. F—— (Case 3) and Mrs. C—— (Case 4), to excise the growth and remove the whole of the disease? When the disease is limited to that part of the œsophagus immediately behind the larynx, and there is no involvement of lymphatic glands, then one might consider the propriety of performing a radical operation with the object of attempting a cure. In neither of the cases just mentioned could such a procedure be thought of; for, as is usually the course of events in such circumstances, both patients allowed the disease to advance too far before they were seen. This is, however, not always the case, and the enterprising surgeon has not been always satisfied by simply supplying the patient with food through a wound in the neck or stomach, but he has on several occasions attempted a radical cure by excising portions of the œsophagus. One of the most successful œsophagectomies was performed by Czerny in 1877, when he excised a small portion of the canal along with a carcinomatous growth with a good result. The lower end of the gullet was united to the wound, and after four months the patient fed herself so conveniently through the fistula in the neck that she refused to have a subsequent operation performed for uniting the divided ends of the œsophagus. Novaro, Billroth, Israel, and von Bergmann also performed this operation, and their patients lived for seven weeks, four weeks, seven days, and one day respectively. Dr. Ashhurst, in his statistics, mentions twelve instances in which œsophagectomy was performed, and he states that eight proved fatal, giving therefore a mortality of 66 per cent. Œsophagectomy has therefore been practically abandoned, unless in very exceptional cases.

The first occasion in which gastrostomy was performed was for the removal of a knife which had been in the

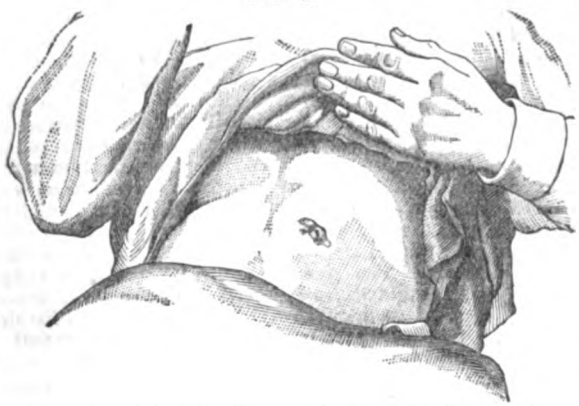
[2] Deutsche Zeitschr. f. Chir. 1882, Bd. xvii., p. 138.

Digitized by Google

stomach for six weeks. Shovel operated in 1635 by making a vertical incision through the left hypochondrium an inch and a half below the ribs. The wound healed well. Between 1635 and 1849 no cases of gastrostomy are recorded. In the latter year Sédillot operated unsuccessfully for cancer of the œsophagus, and from that time until 1876, when Verneuil obtained the first success, the recorded cases constitute an unbroken series of failures. Since 1876, for cicatricial stricture alone, I find 48 cases of gastrostomy recorded, giving 25 recoveries and 23 deaths within a month of the operation; and for malignant disease, 280 operations have been performed, with 126 recoveries and 154 deaths within a month of the operation. Within the last few years gastrostomy has been more successful, probably because greater care has been bestowed upon details, and the operation has been resorted to at an earlier stage in the disease. For example, Knie[3] has operated upon 13 cases with only 3 deaths, and Credé[4] upon 26 cases with 4 deaths.

I cannot occupy time in discussing statistics in detail, or in giving you references, but I would like to tell you the facts which have been impressed upon me in studying the subject, so that you may be guided, as I have been, to know when to operate. In the large majority of the unsuccessful cases the operation was performed too late, and hence we find that a considerable number of the patients succumbed to shock within twenty-four hours, while a large percentage also died from exhaustion, inanition, or extension of the disease a few days after the operation. Within recent years comparatively few deaths have been caused by peritonitis, pneumonia, or septicæmia. The statistics which I have now produced give a very different result from those collected by Verneuil, and published in 1879. He then showed that out of 30 cases in which gastrostomy had been performed for malignant disease, only one survived a month. On the other hand, I find that since 1884 out of 113 cases recorded 80 have lived over thirty days. The most successful cases have been operated upon in one instance by James Murphy,[5] and in another by William Whitehead. The first of these patients lived for 403 days, while the other was alive at the end of the thirteenth month.[6] The operation of gastrostomy, which you have seen me perform successfully on three occasions this session, is the one most frequently employed in cases of stricture which are impermeable to bougies, and in malignant disease. As you observed, the method of operating was as follows: While the patient (take for example Case 3) was under the influence of chloroform an incision was made through the abdominal parietes an inch below and parallel to the left costal cartilages. The incision was an inch and a half long, and extended outwards and downwards from the margin of the left rectus muscle; with some difficulty, on account of the complete collapse of the organ, the stomach was felt. About a couple of square inches of the stomach wall were dragged through the incision in the parietes. A circle of sutures, each including about a quarter of an inch of stomach wall, was passed through the serous and muscular coats. The radius of this circle was about one-third of an inch. Each suture overlapped its neighbours by about one-eighth of an inch, so that when they were all introduced they resembled in form the tyre of a wheel. After all the sutures had been inserted in the stomach wall, the free ends were passed through the subcutaneous tissue and skin and tied externally, so that when the operation was completed an area of stomach wall about the size of a shilling was exposed to view. Through the centre of this area two silver sutures were passed parallel to one another, and about a quarter of an inch apart. This method of stitching, by which the peritoneum and muscular tissue were left free and in full contact with the wall of the stomach, gave a broad base for adhesions and ensured the formation of a complete sphincter. After the operation the patient complained of thirst, but otherwise he was perfectly comfortable. Two-thirds of a grain of morphia were injected subcutaneously between the time of the operation and midnight. The patient was fed upon nutrient digested enemata and peptonised meat suppositories. Five days later a small galvanic cautery was introduced into the stomach between the two silver loops, which were held apart, so as to make a little tension upon the intervening area of stomach. Then a small gum-elastic catheter (No. 3) was passed into the stomach through the opening thus made, and fixed in position by means of adhesive plaster. He was now fed with milk, four ounces being given every two hours, in addition to the nutriment administered by the rectum. Every day larger tubes were inserted, so that a week later a piece of elastic tubing the size of a No. 17 œsophageal bougie was introduced, and beef-tea, milk, masticated porridge, and corn flour were poured into the stomach through a filler by the patient himself. After the food was so taken the tube was withdrawn, the patient remained in the recumbent posture, and held a small pad of gauze over the opening. Within from fifteen to twenty minutes the wound contracted, so as to prevent the escape of the contents of the stomach. Only a ring of mucous membrane, one-twelfth of an inch broad, is interposed between the opening in the stomach and the cutaneous surface. Within a few days this also disappeared. For the last two days the patient has been out of bed.

In respect to the operation of gastrostomy, it is very important to operate in two stages, the first consisting of exposing and stitching the stomach to the parietes, the second of opening the stomach after firm adhesions have formed, so as to obviate the danger of the contents of that viscus escaping into the peritoneum. With reference to the first stage of the operation, a method a little different from that usually employed was adopted. The sutures did not include the peritoneum or muscular tissue, but, from the stomach wall, they passed through subcutaneous tissue and skin only, and were tied externally. By this arrangement a considerable surface of the stomach was left in contact with the sides of the wound in the parietes; the two serous surfaces were not brought together, and so a broad and firm base for adhesion was secured. At the same time the formation of a complete sphincter was assured, as demonstrated by the cases shown. Regarding the second stage of the operation there is nothing worthy of note. The patients now wear elastic tubes always, and no fluid escapes, but if the tube be removed for a quarter of an hour in any of the cases the fistulæ contract, and prevent the passage of the smallest quantity of the contents of the stomach, and so enable the patients to walk about in comfort. The sphincter action is therefore as good as could be desired. In selecting cases for operation the surgeon is very often hampered by the patient refusing to have anything done until he is so reduced in strength that so serious an operation must be attended with danger. Under favourable circumstances, and with due caution on the part of the operator, gastrostomy, when performed in two stages, should not be attended with much danger; but when the patient has allowed himself to reach the last stage of starvation before he seeks the aid of the surgeon, how can a favourable result be expected? The needles used were ordinary sewing-machine needles, round and with an eye in the point. These were fixed on handles, and by heating in a spirit lamp were bent at an obtuse angle and tempered by dipping in oil. The sutures were silk cord, boiled in carbolised wax. The advantage of using a round needle is that it passes easily through the serous and muscular coats, and, when it reaches the more dense submucous layer, the difference in resistance is easily detected, and the danger of passing the suture into the cavity of the stomach is averted. It has been advocated by some surgeons that a double row of stitches should be inserted, but the disadvantage of unduly increasing the number of sutures employed is that the operation becomes very prolonged, and thereby the danger of death from shock is increased. One row of sutures is quite sufficient to keep the parts in apposition until adhesions form.



When the stomach has been empty for a considerable time, it is found to be situated to the left of the middle line, the pylorus occupying a position close to the left margin of the rectus muscle, while the bulk of the organ is drawn up under the arch of the diaphragm. Consequently, in cases of stricture of the œsophagus, where the patient has been starved, the stomach is not to be looked for in its normal position. Labbé recommends an incision two inches in length extending from the left linea semilunaris outwards, parallel to and half an inch below the costal cartilages. Durham advises a vertical incision to be made three or four inches in length over the upper part of the linea semilunaris, while Sédillot makes a crucial incision through the upper part of the left rectus. Again, Hahn of Berlin recommends the following operation which he has performed

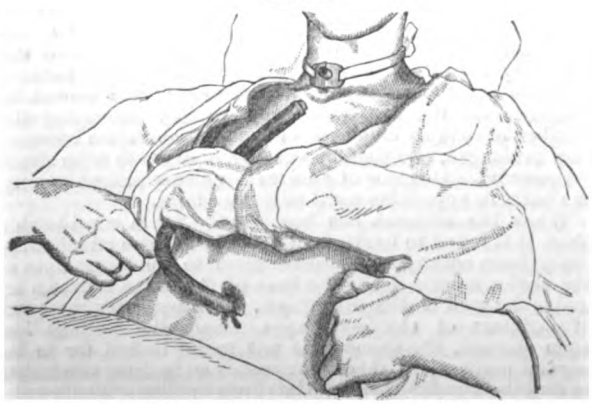
Digitized by Google



in eight cases. An incision is made parallel with the lower edge of the last lower rib and the abdominal cavity opened. A second incision is made in the eighth intercostal space, close to the juncture of the eighth and ninth costal cartilages, through skin and muscular tissues, in a direction obliquely from above downward and outward. The parietal peritoneum at this point is punctured by a pair of curved dressing forceps, or incised; this is enlarged by spreading the forceps. The thumb and index finger of the left hand are introduced into the first-made abdominal wound, and the stomach sought for at a point corresponding as nearly as possible to the fundus. This is grasped by the dressing forceps and drawn through the eighth intercostal space, until the stomach wall overlies the surrounding integument for the space of one centimetre. After covering the wound made first with antiseptic gauze, the stomach, in case the opening is to be made at a subsequent sitting, is sutured by means of its serous covering only to the edges of the wound. In case it is to be opened at once, the serous, muscular, and mucous coats are together attached to the opening in the intercostal space. The abdominal wound is then sutured. After numerous trials upon the cadaver, Hahn found that there was no danger of wounding the diaphragm if care was taken to always select the space between the cartilages of the eighth and ninth ribs, inasmuch as the former has its attachment to the cartilages of the seventh rib towards the median line, acting in such a manner as to leave the eighth intercostal space uncovered and free for operation.

FIG. 1.

Case of cancer of the œsophagus at the level of the lower edge of the cricoid cartilage (Case 3). The illustration shows the gastrostomy wound with the feeding-tube withdrawn, and the complete sphincter action of the muscles of the parietes, by which action no food escaped externally. If the patient lay on his back for a few minutes after taking food he could afterwards walk about with freedom. The gastrostomy was performed on Nov. 6th, 1890, and the patient enjoyed good health till the end of the following July. During the autumn he lost flesh and became very weak; no involvement of lymphatic glands; tumour in œsophagus remained stationary. He was readmitted to the Royal Infirmary on Nov. 5th, 1891, and died on the following day from syncope and congestion of the lungs. Post-mortem examination: No great laryngeal obstruction, no glandular involvement or secondary formations. Microscopic section proved the tumour to be a scirrhous cancer.

FIG. 2.

Case of epithelioma of the œsophagus behind the cricoid cartilage (Case 4). Gastrostomy was performed on Jan. 29th, 1891, and tracheotomy on March 28th, for œdematous laryngitis. The illustration shows feeding and tracheotomy tubes in position. The patient improved during the spring and summer months, but when seen in October the cervical glands were involved and the larynx obstructed. She has not been seen since October.

FIG. 3.

Epithelioma of the lower end of the œsophagus (Case 7). The illustration shows the feeding tube withdrawn. Sphincter action was very complete, so that the tube could not be left out for more than a few minutes. The patient progressed favourably during the early summer, and the disease advanced very slowly; but not receiving proper attention at home, he was found dead in bed from starvation.

The advantages claimed for the operation are as follows:—1. A small and contracted stomach can with greater ease be drawn forward and attached at this point. 2. The attachment seems to be more reliable than when made to the edges of the abdominal wound. The contents of the stomach, on account of the better closure of the opening, do not come into contact with the wound to the same extent as in the older methods. 3. The feeding of the patient can be better accomplished; the closure of the space by the approximation of the ribs acts as a pinch-cock, thus preventing fluids from finding their way out alongside of the feeding-tube. 4. No obturator or other means of closing the opening later on is necessary. A gradual dilatation of the fistula, owing to the resistance offered by the cartilages of the ribs, cannot occur.[7]

By the results of the statistics of recent operations the surgeon is certainly encouraged to resort to gastrostomy as soon as the patient is unable to take sufficient food by the mouth, in those cases where it is inadvisable or impossible to feed him by tubes.

A CASE OF SYRINGOMYELUS.

BY J. HUGHLINGS JACKSON, M.D., F.R.S.,
AND
JAMES GALLOWAY, M.A., M.B.

THE patient, Mary H——, aged forty-seven, is a stout healthy-looking woman. Her grandfather died at an advanced age in the Bethnal-green Infirmary, suffering from a nervous disease which caused contraction of the lower extremities. Her father and mother are alive and in good health. The patient's paternal aunt suffered from rheumatic fever, and her sister died in the London Hospital of heart disease following rheumatic fever. The patient was born in London, but spent part of her childhood in the United States. She has been married twice, and has had ten children. Of these, eight are alive and healthy, and two (twins) died in infancy. No evidence of syphilitic disease nor of alcoholic over-indulgence is obtainable; she has led a careful life, and has enjoyed good health in spite of the nervous affection to be described. Menstruation ceased two years ago.

When twelve years of age, while in St. Louis, U.S., she suffered from a cut on the radial border of the extensor surface of the right forearm, about two inches above the wrist. The tendons were exposed, but the wound seems to have healed after causing very little trouble.

[7] Centralbl. f. Chirg., No. 11, 1890.

Twenty-two years ago, when pregnant, she had an attack which she calls sunstroke, while in the garden on a hot summer afternoon. On this occasion she remained unconscious for two hours and was under medical treatment. After this attack she observed that she was gradually losing sensation in the right arm and hand, and on the right side of the body. She is not quite certain that there was not some loss of sensation in this region even before the attack mentioned. The impairment of sensation increased, and she soon observed that there was loss of power in the forearm and hand, especially affecting the third, fourth, and fifth digits. Having to grasp objects by the right thumb and forefinger she felt awkward at work, and the arm became easily fatigued. Fifteen years ago she received a severe scald on the right forearm, and her attention was especially attracted to the loss of sensation about this time. Since that time she has frequently burnt and otherwise injured her right fingers and arm, being unable to feel that water was too hot for washing in. On a recent occasion she pinned her shawl into the skin of her right breast, and was unaware of the injury inflicted till some time afterwards. Twelve years ago she sustained a laceration of the skin over the right elbow. She thinks she poisoned the wound by removing a piece of skin with a pair of rusty scissors. There resulted considerable inflammation round the elbow, and an abscess, forming in the right axilla, was opened and treated in the ordinary way. For two years and a half at least she has noticed that the third, fourth, and fifth fingers have been contracted and stiff. Eight months ago, while wringing clothes in the awkward manner referred to—grasping by the right forefinger and thumb, resting the elbow on the edge of the tub and using the left hand—she suddenly noticed a cracking sound in the right elbow, and had to stop work on account of pain in moving the joint. The same night the right elbow swelled greatly, and remained large for many months. She says the elbow became "dropsical," and she has been unable to use the joint effectively since that day.

In September, 1891, she was admitted to the London Hospital under the care of Mr. Waren Tay. The condition of the right elbow exactly resembled that observed in Charcot's joint disease, but no signs of tabes dorsalis were discovered. The arm was placed on a splint, the fluid became absorbed, and the elbow diminished in size. The joint, in spite of the great changes observed, was uncomfortable rather than painful. On leaving the surgical wards she was transferred to the care of Dr. Hughlings Jackson. The following conditions may now be observed: The right elbow and forearm are considerably larger than the left. The right elbow-joint is quite disorganised, and there is some, though not excessive, osteophytic growth in the neighbourhood of the joint. The forearm can be moved laterally at the joint for about a quarter of an inch with much grating. Movements at the elbow cause a little discomfort, but little or no pain; complete extension is impossible on account of the altered relations of the joint surfaces; the other movements are abnormally free, and are attended with grating in the joint. The right wrist has also been somewhat swollen, and slight grating can be obtained on movement. The third, fourth, and fifth digits of the right hand are permanently flexed and contracted, the second and first digits show similar changes, but not to the same extent. Wasting of the thenar, hypothenar, and interossei muscles is well marked. (Fig. 1.)

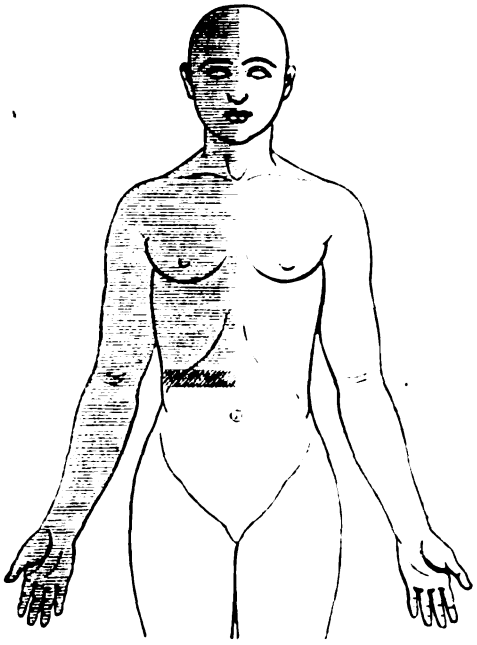
The following results of the reactions of the affected muscles to electricity are communicated by Dr. James Taylor: "All the muscles of the affected side, including the facial muscles, react to the interrupted current, but the current required to produce the reaction is greater than that required for the muscles of the (left) unaffected side. This difference in reaction is most marked in the small muscles of the hand. To the continuous current, similarly, a greater current is required to produce a reaction, but there is no qualitative change. K.C.C. is always greater than A.C.C." Over an area, including the front and back of the right upper extremity, the right side of the scalp, face, and neck, and the right side of the trunk to about the level of the tenth dorsal vertebra there exists marked alteration in sensation. The patient cannot distinguish between painful sensations and contact. Thus she cannot tell the difference when the skin is touched with the finger or the sharp points of a pair of compasses. The locality is readily distinguished, but both tests appear as if "a weight" had been placed on the part. Over this region, also, the patient cannot distinguish between heat and cold. She feels and localises the point of contact when hot and cold objects are applied, but cannot tell which is the hot or which the cold object. The muscular sense in the arm is retained. At the level of the tenth dorsal vertebra on the right side there is a region about one inch in breadth where the markedly altered sensations shade rapidly into normal sensation. In the middle line the limit of altered sensation is well marked. The sensation of the mucous membrane of the right side of the tongue, mouth, palate, and fauces is affected in a fashion similar to that of the body. A touch can be readily localised, but a painful sensation is felt only as a touch.[1] The sense of smell seems to be less acute on using the right than when using the left nostril, and there seems to be slight diminution of taste on the right side of the tongue, but the results obtained on examining these special senses are not very trustworthy. The senses of sight and hearing

FIG. 1.

Engraving to show the position assumed by the right hand. From photograph. (Mary H——.)

are normal. There is no alteration in the movement of the eye, and the fundus oculi is normal. The lower extremities are normal in all respects, and beyond a slight systolic murmur at the base of the heart no other morbid phenomena are noticeable. (Figs. 2 and 3.)

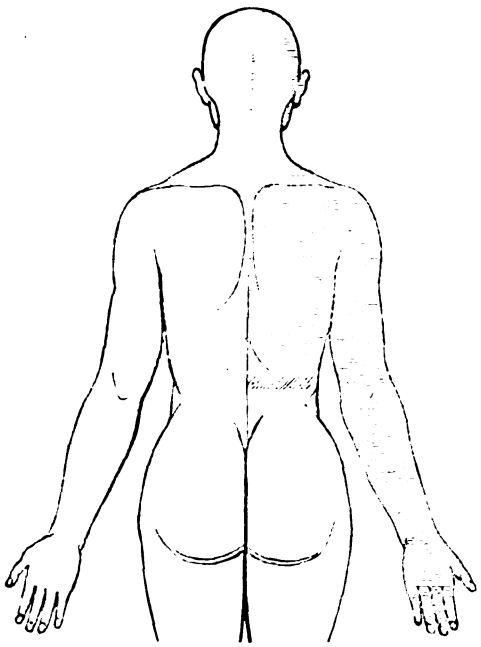
The lesion characteristic of syringomyelus appears to be of congenital origin, and consists essentially of a mass of neuroglia situated in the deeper parts of the posterior fissure of the spinal cord, behind the central canal. The quantity of the abnormal tissue varies greatly in amount in different cases, and at different levels in the same case. This variation is due probably to two causes—to the amount which persists originally after development ceases, and to the increase which this original quantity subsequently undergoes. The cavity from which the disease is named is probably in the first instance nothing more than the early posterior extension of the central canal of the cord, which has failed to become filled up. At the same time, the existence of the embryonic neuroglia in this position probably interferes with the proper development of the posterior columns of the cord. The case now recorded emphasises the fact that the condition mentioned may exist for long in the cord, simply as a deformity, without causing evident symptoms. As has been noted, the patient refers to a period at least twenty-two years ago as the date of commencement of her present symptoms. During the twenty-five years of her life preceding that period she had suffered from no sign of the disease. In a case recently described by one of us (Dr. J. Galloway), typical lesions of the disease were found in a patient aged forty-three, who had been in robust health till two years before death, which occurred from the exhaustion following acute mania, and only a few weeks before



[1] To this striking "abolition of sensibility to pain and to temperature, with preservation of sensibility to contact and to the muscular sense," Professor Charcot proposes to apply the term "dissociation syringomyélique." Bruhl: Contribution à l'Etude de la Syringomyélie. Paris, 1889, p. 14.

Digitized by Google

death were any symptoms noted pointing to a lesion of the spinal cord.[2] (Figs. 4 and 5.)



It is important to observe that the early signs, before marked degenerative changes in the cord supervene, consist of the loss of sensation to pain and of the power of distinguishing between heat and cold, while the ordinary contact sensation remains practically intact. This is of interest, as so far as is known at present the conducting tracts for painful sensations, at all events, exist in the lateral columns, while the degenerative changes which result from the increased growth or necrosis of the neuroglia mass are shown most prominently in the posterior columns and in the grey substance of the cord. (Fig. 6.) The alteration in sensation in this case involves the head and neck, the area of distribution of the cutaneous branches of the upper cervical nerves, and of the fifth cranial nerve. This phenomenon is a somewhat rare symptom of the disease, but it is well known that the lesion may continue upwards through the cervical cord, under and involving the floor of the fourth ventricle, and even into the third ventricle, associated with dilatation of the lateral ventricles of the brain. A case very similar to the present is recorded by Dr. Bruhl in his recent work on this subject. In the case referred to the diagrams of altered sensation are almost identical with those appended to the case now described.[3] The case of our patient affords also an example of an acute arthritic degeneration occurring during the course of syringomyelus; the condition of the joint is now exactly similar to the well-known arthropathy so often met with in tabes dorsalis. Although the patient had an axillary abscess it was probably of infective origin, and had nothing in common with the painless collections of pus especially occurring on the fingers described by Morvan, and now considered to be associated with certain forms of syringomyelus. It is interesting to note also in this connexion that in spite of the fact that the patient has frequently received injury on the right arm, no abscess or "whitlow" has occurred except in the single instance above referred to. The question of the identity of certain forms of syringomyelus and anses-

thetic leprosy has recently received attention in France.[4] In this particular case the absence of trophic disturbances characteristic of the form of syringomyelus described by Morvan, as well as the fact of the anæsthesia existing in such a well-marked area without any tendency to a macular arrangement, preclude the suggestion of the diagnosis of leprosy in this case, and emphasise the fact that syringomyelus is a much wider disease than the forms of it distinguished by trophic changes, and in this wider category we believe the case under consideration has a place. It may be of interest to mention that a patient presenting many symptoms of syringomyelus was shown at a recent meeting of the Neurological Society by Dr. Ferrier. Of this important case we learn that Dr. Ferrier's diagnosis has been verified by necropsy since he exhibited the patient. A very complete bibliography of the cases reported both in English and foreign literature will be found in the works already quoted by Bruhl and Verchère.

REMARKS ON THE OPERATION OF EXCISION OF THE BREAST AND ITS AFTER-TREATMENT.

BY A. PEARCE GOULD, M.S.,
SENIOR ASSISTANT SURGEON, MIDDLESEX HOSPITAL.

IT may be thought that some apology is due for offering to the profession any remarks upon a subject so trite as the operation of excision of the breast. But surgeons recognise the importance of paying attention to small details, and I venture, therefore, to refer to points in the conduct and after-treatment of this operation, attention to which has in my hands been followed by greater comfort and more speedy recovery of the patients. I will not occupy the valuable space of this journal by a new description of the old operation of excision of the mamma, but will at once deal with certain special points.

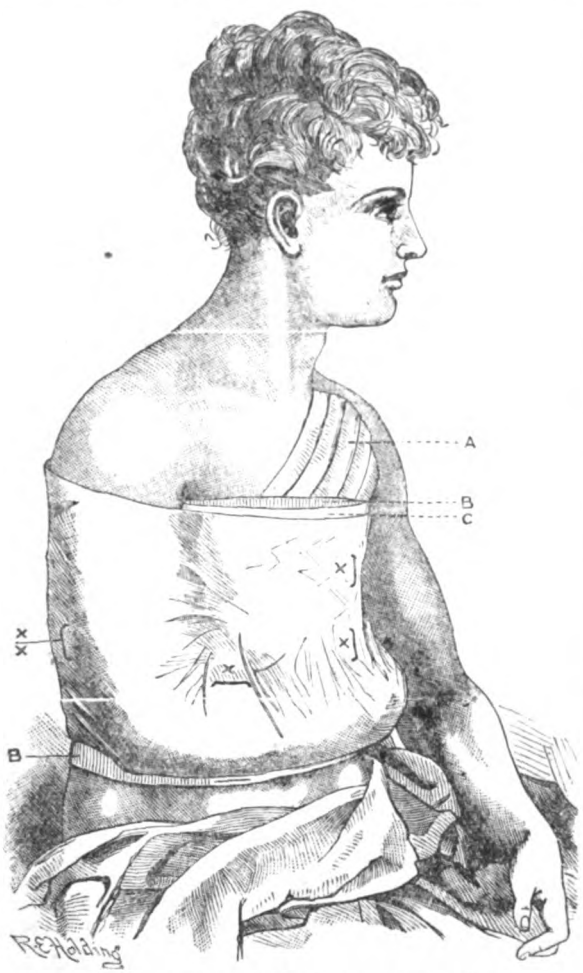
1. *The Incision.*—Some difference of opinion exists as to the best direction for the elliptical incision which is almost invariably employed. In a clinical lecture published in THE LANCET of May 9th, 1891, Mr. Christopher Heath discusses this matter from the point of view of the more or less perfect drainage of the wound which can be obtained. Another point considered to be of importance is the ease with which the incision can be prolonged into the axilla for the removal of infected glands. I would submit that neither of these considerations need have any weight with the surgeon. There is no wound which is more easily and uniformly treated without resort to any means of drainage than that left after removal of the breast and axillary glands. It is sometimes convenient to prolong the incision into the axilla, but it is never necessary to do so, for it is quite easy to clear out the axilla completely through the wound made for removal of the mamma. Quite recently, I have had to operate upon two cases of scirrhous tumour situated in the upper portion of the mammary gland, and I made my incisions so that the long axis of the ellipse of skin removed was vertical. In both cases it was quite easy to remove the whole of the axillary fat and glands through this incision. This is the most extreme case. Two considerations only should guide the surgeon in planning his incisions — one paramount, the other of secondary importance. The first is the complete removal of the nipple and the skin over the tumour when that is malignant; the second is to have the cicatrix parallel to the fibres of the pectoralis major. In most cases these two objects are best attained by the same incision—one enclosing an ellipse of skin parallel with the anterior fold of the axilla when the arm is at a right angle with the trunk.

2. *The Axillary Glands.*—When the mamma is not the seat of a malignant growth, of course the surgeon will not invade the axilla, and even when the disease is sarcoma, the axillary glands should not be removed unless obviously diseased. During the last year I operated upon two patients with sarcoma of the breast, in whom secondary growths occurred in the axillary glands. But in cases of carcinoma of the mamma I am strongly of opinion that it is the surgeon's duty, as a matter of routine, to remove all the axillary glands in their packing of fat. When I first made this assertion, in a paper read before the Medical Society of London, March 27th, 1882,[1] I was mainly influenced by theoretical considerations. Since then I have had, and seen, several cases where disease could only be recognised in the axillary glands after their removal, because it existed in foci of the size of a white mustard-seed or peppercorn. I have followed this practice in every case of operation for cancer of the breast since 1880, and have never had cause to regret it. Where the glands are obviously diseased all surgeons are agreed that they should be removed, and difference of opinion only arises in the cases where no enlargement of the glands can be detected. It is assumed that in such cases no glandular disease exists, and it is asserted that the removal of the glands is an unnecessary extension of the operation and an additional danger. But the assumption is not well founded; for it is only when careful examination of the glands after removal has shown them to be free from cancerous infiltration that we can be sure that they are not infected, and then it must be remembered that it is just in these cases that the axillary glands can be removed with practically perfect safety. There is no adhesion to vessels, muscles, or bone to render the operation hazardous. It is useless to refer to statistics in this matter. The cases where in the past the glands have been excised as well as the mamma, of course, show a rather longer convalescence, and even a higher mortality than those where only the breast has been excised, for they include all the severer cases, such as those requiring extensive dissection, and those where the glands are adherent to the axillary vessels or their large branches. But where the glands are not obviously diseased there is no risk of wounding any important vessel or nerve, and their free removal in no way adds to the danger of the operation if the wound is aseptic. It is best to remove the axillary glands and fat in one mass, first separating it from the pectoral muscles, then from the serratus magnus, then from the subscapularis, and lastly from the vessels on the outer side. The fat should be removed quite up to the clavicle, as the chain of glands extends up to that bone. A raspatory is the best instrument to use when anything more than the finger is needed. The intercosto-humeral nerve should be preserved, and this can easily be done in all cases where the glandular infiltration is limited.

3. *Arrest of Hæmorrhage.*—The most convenient plan is to pick up with pressure forceps any spurting arteries as they are cut, and then, when the breast is detached from the pectoral muscle, to carefully search for any smaller bleeding points and treat them in the same way. Then proceed with the clearance of the axilla, and if any artery is divided, seize it also with forceps. Now remove the forceps in the order in which they were put on, taking great care not to open up the compressed ends of the arteries. Occasionally one or more arteries will require to be twisted—a ligature is never necessary. Sponges should be used only to dry the wound, and should never be rubbed over it; the less they are used the better. No bleeding point, however small, should be neglected.

4. *Irrigation.*—The wound should be thoroughly flushed with a solution of bichloride of mercury (1 in 2000), after the hæmorrhage has been arrested. I generally use four or five quarts of the solution, and find it a good plan to flush the wound with it just before fastening the last suture. Care must be taken to express all the fluid, and if this is done there is no fear of corrosive sublimate poisoning. Besides its action as an antiseptic, this solution is a valuable astringent, and greatly diminishes the subsequent serous exudation, and in this respect is far superior to carbolic acid solution.

5. *Suture and Drainage.*—I have obtained the best results with a continuous suture of the finest chromicised catgut introduced at intervals of half an inch, and each loop caught up—the button-hole stitch. A drainage-tube should not be employed.



6. *The Dressing.*—The dressing should fulfil two conditions. It ought to be aseptic, and it should secure exact apposition of the wound surfaces without any movement, until primary adhesion has taken place. The rounded, firm, and yet elastic chest wall is admirably adapted for a surface of

counter-pressure. Immediately over the wound I place a fourfold dressing of boric lint, large enough to extend about an inch in all directions beyond the wound surface. This is fixed in place by strips of strapping, cut two inches wide. They are fixed to the back at the level of the spine of the scapula, passed round the chest to the opposite shoulder, and put on from the lower edge of the dressing up to the anterior fold of the axilla. They are applied sufficiently firmly to keep the flaps of skin well and evenly pressed against the thorax, and so prevent any bagging in the wound. Over this a dressing of alembroth gauze or wool is fastened on with a roller bandage carried round the trunk in an ascending figure-of 8. Lastly, the arm is fixed to the side, with the forearm lying across the trunk, the elbow bent at a right angle. This should be done by means of a sling, not by bandages. The best sling for the purpose is a

A, Strapping. B, Figure-of-8 bandage over outer dressing. C, Sling, showing its two folds. ×, Pins fastening the sling to the bandage.

common chamber-towel folded in two lengthwise. The forearm and arm are dropped between its two layers, the hand being just within one end, and then the other end is passed round the back under the opposite arm, and the two ends are pinned together and to the underlying bandage. Additional pins should be placed behind the arm and above the forearm. In this way the arm and forearm are securely, evenly, and comfortably fixed, and by removing two or three of the pins the outer layer of the sling can be turned down, and the hand and forearm washed every day, without in the least disturbing the position of the arm and the rest of the dressing. One special feature of this dressing is that there is no bandage or sling over the shoulder or round the neck—a most important matter for the patient's comfort, as the head and neck can be moved quite freely. A bandage passed round or over the neck is more than uncomfortable—it is inefficient, for it is sure to get loose.

The *after-treatment* can be dismissed in a few words. The first trouble to combat is the pain in the back, which inevitably comes on when a patient lies in bed with the arm fixed to the side. For the first twenty-four hours a firm pillow should be carefully placed under the arm of the affected side so as to support it well; this may be entirely successful in relieving the pain. After the first day I like the patient to be raised into a sitting posture, well supported by pillows or a bed-rest; this at once relieves the pain. On the second and each successive day the sling should be gently turned back; and while one hand is placed upon the arm to keep it fixed against the chest, the fingers, wrist, and elbow should be flexed and extended, then washed, dried, powdered, and again fixed in the sling. This is a great refreshment to the patient, and in no way disturbs the wound or the dressings over it. On the fourth or fifth day, if all is well, the patient may get up and sit on a chair. On the seventh day the dressing should be removed, care being taken in turning back the deepest part of it not to break down the union of the wound edges and surfaces. As a rule union will be found complete if the edges have been brought into exact apposition without undue tension, and if the dressing has been affixed with the requisite amount of pressure. All the stitches should be cut and gently removed, and the tender cicatrix should be protected by a dressing of a double layer of sublimate gauze fixed on with collodion, and over that a light boric lint dressing may be fastened by a figure-of 8 bandage round the body. The patient, if in a hospital, may now go home and return in a week for the removal of this dressing, when, if the cicatrix is firm, no further treatment will be needed. It is not necessary or wise to keep the arm fixed to the side after the first week; there will not then be any troublesome stiffness of the shoulder afterwards. In his recently published "Manual of Operative Surgery" Mr. Treves states that "the patient may usually be ordered up on the eleventh day, and may leave the hospital on the fourteenth." As stated above, I have found it not only possible, but desirable, to allow my patients up much earlier than this, and lately they have, as a rule, left the hospital before the tenth day, some of them on the eighth day.

I append very brief notes of the cases of excision of the mamma under my care in the Middlesex Hospital last year up to the time of my leaving for my annual holiday. These cases were treated in the manner described above. In all except Cases 1 and 2 the axillary glands and fat were removed.

CASE 1.—Alf. D——, aged forty-nine. Cystic tumour of breast; operation on Jan. 23rd; got up on Jan. 27th.—Jan. 31st (ninth day): Dressings and sutures removed; wound healed except at two small points, where edges had not been brought into perfect apposition. Went home same day.

CASE 2.—Emma S——, aged forty-two. Multiple involution cysts of both breasts; right breast removed on March 28th—April 4th: Dressings and sutures removed; wound entirely healed.—6th (tenth day): Left hospital. This patient returned ten days later.—17th: Left breast excised.—23rd: Dressed; sutures removed; wound entirely healed. She stayed in hospital until May 4th on account of rheumatic pains in the shoulder.

CASE 3.—Emma Y——, aged sixty-three. Scirrhus of right breast and axillary glands; operation on May 7th.—15th: Dressed; sutures removed; wound entirely healed.—18th: Left the hospital.

CASE 4.—Frederick H——, aged forty-one. Scirrhus of right breast and axillary glands; operation on May 9th.—16th: Dressed; sutures removed; wound healed, except two small spots where edges had not been brought into exact apposition.—17th: Went home (ninth day).

CASE 5.—Annie B——, aged sixty-two. Scirrhus of left breast and axillary glands; operation on June 27th.—July 3rd: Got up—4th: Dressed; sutures removed; wound entirely healed. The patient left the hospital on July 6th.

CASE 6.—Mary W——, aged fifty-three. Sarcoma of right breast and axillary glands; operation on July 15th.—July 20th (sixth day): Dressings and sutures removed; wound entirely healed.—21st (seventh day): Went home.

CASE 7.—Emily B——, aged forty-two. Scirrhus of left breast and axillary glands; operation on July 20th.—25th: Got up.—26th: Dressed; sutures removed; wound entirely healed.—27th (eighth day): Went home.

SUBPERITONEAL HYSTERECTOMY.[1]

BY HEYWOOD SMITH, M.A., M.D. OXON.

IN giving the above title to this paper I have not aimed at its being accurately descriptive. A more proper title would be "An Intra-pelvic yet Extra-peritoneal Treatment of the Stump in Cases of Hysterectomy." I propose briefly to sketch the methods most commonly in use for the treatment of the cervical stump, quoting from the papers and speeches of various operators, to quote some cases of intra-pelvic treatment of the stump by those who have so operated, then to narrate those cases in my own practice, and finally to make some observations which I hope will tend to show the intra-pelvic and extra-peritoneal method will eventually become *the* method of treatment, where practicable, in cases of fibrous tumour of the uterus. In dealing with the stump in supra-vaginal hysterectomy we are brought to face a totally different condition than we have in the pedicle of an ovarian tumour, for we have to manipulate a stump composed of contractile tissue, which by its shrinkage, when constricted as a whole, relaxes the pressure on the vessels and opens up the danger of fatal hæmorrhage. To obviate this danger the majority of operators prefer to bring the stump outside the abdominal wound, where it is open to observation and can be further constricted from time to time as necessity requires. If, however, we can carry out a method whereby the vessels can be effectually secured, and at the same time do away with the disadvantages of the clamp, we shall, I venture to think, see our cases get well more rapidly and our patients less exposed both to danger from septic absorption as well as to inconvenience from tension on the stump and the abdominal wound and from the inevitable crowding of the bladder.

A case was reported by Dr. Christian Fenger to the Gynæcological Society of Chicago in 1888, which, though a pedunculated fibro-cystoma, yet involved the suturing of uterine contractile tissue. This case recovered after some suppuration in the stump. Dr. Bantock exhibited a tumour before this Society in 1888, where, after its removal, an enormous surface was left. After tying many bleeding points he stitched the anterior half of the peritoneum to the posterior, completely obliterating the raw surface. He also, in 1889, brought before the Society a case of fibroid of the uterus removed by Dr. Vincent Jackson of Wolverhampton. In this case peritoneal flaps were stitched over the cut surface. In vol. v. of the *British Gynæcological Journal* Dr. Rakuza of Odessa reports five cases of supra-vaginal amputation of the uterus with three recoveries, and two deaths from peritonitis. In 1890 Mr. Reeves brought forward a case where, after tying the broad ligaments, he tied each uterine artery separately, and treated the stump after the intra-peritoneal method. In the *Medical Press* of Nov. 25th and Dec. 9th, 1891, Mr. Reeves has published a paper on Hysterectomy in which he advocates this method of operating, giving two cases. He quotes a Dutch operator who had had forty-four cases with four or five deaths, and Dr. Chrotak of Vienna, who had done ten cases, all successful. At a meeting of the Gynæcological Society of Chicago, January, 1890, Dr. Henry Byford introduced a new method, that of vaginal fixation of the stump, where the end of the stump is brought into the vagina through an opening made in the anterior fornix. At a meeting of the American Gynæcological Society, Dr. Skene suggested "dilatation and inversion of the cervix," which would fulfil the indications without wounding the vagina. In the *American Journal of Obstetrics* for April, 1890, there appeared a paper by Dr. James Goffe of New York on "A New Method—the Intra-abdominal but Extra-peritoneal Method of disposing of the Pedicle in Supra-vaginal Hysterectomy for Fibroid Tumour, with Report of Four Successful Cases." His method of operating was shortly as follows: Anterior and posterior flaps were stripped off the uterus, the stump transfixed and tied inside the flaps, and the whole stitched over with catgut. Dr. Goffe says: "In regard to the operation itself, while each of the different features has been used by different operators, I know of no one having combined them all into a systematic method till I did so myself. The advantages are that it has all the elements of safety that any of the operations in use have, and, I believe, more; moreover, it leaves no ligature in the pelvis to give trouble, and, above all, it restores the organs to their proper relation in the pelvis." Mr. Meredith, in his paper read before the Medical Society in 1890, indicates the possibility of securing the uterine stump intra-abdominally. In the discussion that followed Mr. Treves said: "The bloodvessels going to the mass were easy to find and to ligature. Having secured these, the ligaments on each side were divided and a V-shaped section of the cervix was made, leaving a kind of flap on each side. When the tumour was removed in this manner a large gash was made in the peritoneum, and after this was stitched up there remained a closed seam running across the pelvis." Mr. Lawson Tait, after criticising this method of operating, went on to say: "We all know perfectly well that if we could secure the vessels in our stumps effectually, and then drop the stump back in the abdomen, we should have at once, in all probability, a 5 or 6 per cent. mortality for these dreadful operations." Dr. Elder of Nottingham said "he was quite at one with Mr. Treves in regarding the clamp as the relic of a barbarous age, and thought the day was not far distant when it would be relegated to the limbo of antiquity and its use superseded by an intra-peritoneal method more in accordance with the advanced surgery of to-day." In THE LANCET of Nov. 29th, 1890, there appeared a paper on "Supra-vaginal (Abdominal) Hysterectomy with the Scissors, a Contribution to the Discussion on the Treatment of the Uterine Stump," by H. N. M. Milton of Cairo. He shows that the blood-supply can be efficiently controlled, even when the vessels are large, by ligaturing them separately. He then describes the formation of the anterior and posterior flaps, showing that by separating the peritoneum from the sides of the cervix at the points of union of the incisions all fear of injuring the ureters may be avoided. He then narrates three cases in which he thus operated with success. In THE LANCET of Sept. 26th, 1891, he writes that he has been successful in a fourth case. Dr. Widenham Maunsell of Otago, New Zealand, described in 1887 an intra-peritoneal operation where he sewed the peritoneal flaps over the stump, but he also closed the cervical canal by vivifying its sides, a method which I venture to think unadvisable, as closing the natural exit to any pus that might be formed. Dr. Sinclair, in a letter to the *British Medical Journal* of Nov. 14th, 1891, describes the intra-pelvic operation, "finishing the stump like a plastic operation." His cases, ten or twelve, all recovered.

I will now briefly relate my own experience.

CASE 1.—S. T. W——, aged thirty-five; married nineteen years, never pregnant; admitted into Warrington Lodge, Aug. 28th, 1890. Tumour first felt two years ago; grown rapidly; constant pain; first flooding one year ago. Operation, cælio-hysterectomy. Long incision, tumour drawn out of abdomen, elastic ligature placed round its base, uterine wall cut round about one third up, and tumour shelled out of its bed in the cervix; uterine arteries tied separately; stump mopped over with hot carbolised oil. The peritoneum was sewn over the stump with an uninterrupted suture of China twist with Lembert's stitches. Operation lasted eighty minutes; tumour weighed six pounds. Temperature rose on second day. On the sixteenth day after the operation, as the temperature indicated pus, I passed a sound carefully up the cervical canal and evacuated a quantity of thick offensive pus. (I had not at that time seen Dr. Goffe's paper where he had the same experience.) Patient discharged well thirty-six days after operation.

CASE 2.—J. H——, aged thirty-five; married ten years; no children; admitted Feb. 24th, 1891; ailing seven years. Tumour felt two years and a half ago. Operation, cælio-hysterectomy, Feb. 27th. Long incision; two large tumours continuous with one another drawn out of pelvis; broad ligaments clamped on each side with long pressure forceps and divided; elastic tube passed round the base of the tumour, which was then cut away; cut surface large, contracted rapidly; profuse hæmorrhage; uterine arteries ligatured with chromicised catgut; whole length of raw surface from the end of one broad ligament to the other laced with an uninterrupted chromicised catgut suture, the stitches over the stump being Lembert's. On the fifth day the temperature rose, and on the eighth day it was 103·4°. There was a large swelling on the right of the pelvis; by

[1] Abstract of a paper read before the British Gynæcological Society on Feb. 11th, 1892.

Digitized by Google

aspiration it proved to be a hæmatocele; free incision and some offensive, broken-down blood-clot evacuated. This had to be done more than once, but the patient eventually did well. The occurrence of this hæmatocele, which was large, affords a good proof that if the peritoneum is well sutured it heals quickly and so firmly as to withstand the pressure of fluid (blood or pus) upwards without giving way.

CASE 3.—A. H——, aged forty-six years and nine months; married twenty years and nine months; one child aged twenty. Had been under the care of a specialist at one of the large general hospitals, who said he could do nothing for her. Admitted May 27th, 1891. Uterus jammed up on the right anterior aspect of the pelvis by a large hard tumour. Operation on June 3rd. A long incision below the umbilicus was made, the front of the tumour covered with the left broad ligament; this was tied and divided. The tumour, which is unusual in fibroids, was extensively adherent to the bottom of the pelvis. It was separated and drawn out of the abdomen, an elastic ligature was passed round the cervix and the tumour peeled off the uterus, which was considerably torn; the peritoneal flaps were then made, the cervix transfixed and tied inside the flaps, and the uterus cut away. The pelvic peritoneal wound was closed as in Case 2. A sponge wrung out of tincture of matico was temporarily packed into the pelvis. A glass drainage-tube was inserted, which was removed on the third day. The operation lasted ninety-five minutes. Indications of suppuration supervened, the os uteri was dilated, and the silk ligature that was round the cervix and the catgut ligature of the uterine artery came away. In this case the closed peritoneum over the uterine stump held and resisted the suppuration of the cervical tissue going on just below it.

I will now briefly sum up the lessons to be learnt from the cases: (1) That, where it is possible of application, the subperitoneal method holds out as good a prospect of success as any other, and leaves the other pelvic organs free and unfettered by any constriction or adhesion; (2) the best methods, it appears to me, are those of Dr. Goffe and Mr. Milton, and so far carried out in a modified way by myself. The main points in the operation seem to be: (1) Make the peritoneal flaps sufficiently large, as they can be reduced, but not added to; (2) secure absolutely every bleeding branch of the uterine arteries, if possible, separately; (3) lace the whole pelvic peritoneal wound across with an uninterrupted suture of chromicised catgut, taking care that Lembert's stitches are used over the uterine stump, so that it is entirely sealed with peritoneal covering.

It is recommended that the cervical stump be divided as low down as possible, for the proportion of connective tissue to contractile tissue is greater than in the upper part of the uterus. There will therefore be less shrinking the more the amputation is carried through the cervix proper. I would also point out the great advantage of using tincture of matico as a styptic where there is any oozing. It is very effectual, and seems to do much less harm than others. There remain three points for discussion: 1. Shall we use a drainage-tube? Where there is any oozing, Yes; but where the pelvis, after the lacing, remains dry, No. 2. Shall the cervical canal be destroyed by caustics? Shall it be transfixed and tied, or shall it be left free? If the bloodvessels are quite secured, No, as such ligature tends to set up suppuration within the cervical canal, and if the canal is obliterated the natural exit of any pus that may form is cut off; better leave it free. I here close, and trust that this paper may be the means of calling attention to a method of performing the operation of hysterectomy that, when we have mastered its details, will prove more scientific than the abdominal fixation of the stump, will leave the parts with their relations unaltered, and pain from unnatural tension impossible, and that will give results, as shown in the numerous cases that have recovered among those related in this paper, that, considering the greater gravity of the operation, will compare not unfavourably with those we have arrived at in ovariotomy.

Harley-street, W.

THE New York Health Department officers have, it is stated, found thirty-seven victims of typhus fever among the 267 Hebrew passengers of the steamship *Massalia*, of the Fabre line, from Naples, which landed 717 emigrants on Jan. 30th.

THE TREATMENT OF INOPERABLE MALIGNANT NEOPLASMS BY THE ANILINE DYES.[1]

BY PROF. DR R. VON MOSETIG-MOORHOF OF VIENNA.

TRANSLATED AND MUCH CONDENSED BY F. F. BURGHARD, M.S. LOND., F.R.C.S. ENG., ASSISTANT SURGEON TO KING'S COLLEGE HOSPITAL.

PROF. MOSETIG-MOORHOF thinks it desirable, in consequence of the numerous inquiries made of him and the appeals for the publication of cases, to put on record the results that he has obtained up to the present time in the treatment of malignant growths too advanced for operative relief by the injection of the aniline dyes. In 1883 he injected a 1 per cent. watery solution of aniline trichlorate (free of all traces of arsenic) into a man fifty years of age, who was the subject of a sarcoma of the inguinal region as large as an orange. The injection was repeated every two or three days well into the tumour. In two months' time the mass had decreased to a nodule the size of a nut; it had in part broken down and in part shrivelled up. The man remained well for a year, and then died of an acute pneumonia without any relapse having taken place. Notwithstanding this very successful case the treatment had to be abandoned for a time, owing partly to the unpleasant constitutional effects that were produced and partly to want of material. In 1890 Professor Stilling's pyoktanin (Merck's preparation) was tried, and owing to the fact that it combines a certain amount of antiseptic power with a high degree of innocuousness it has been largely used since. The technique of the treatment is then given at some length. A special syringe, holding from two to three grammes, is used with long and wide cannulæ. A Pravaz syringe does not hold sufficient, and with a small needle greater pressure has to be exerted on the piston. Some special curved cannulæ are used for injections into the tongue. The needle must be most carefully rendered aseptic, and the syringe should be used for no other purpose. An aqueous solution should be used, and should be carefully filtered (if possible, through an aseptic asbestos filter), as it has always a tendency to precipitate, and so block the cannula. To avoid this, also, it is advisable not to use a more concentrated solution than 1 in 500. Disinfect the skin. The cannula should be plunged into healthy skin immediately beyond the tumour, and pushed in deeply towards the edge of the growth. When it has penetrated the latter, the solution should be slowly injected. As much as from two to twelve grammes of the 1 in 500 solution may be injected at each sitting, the injections being made either at one spot or at several, as may seem necessary. Where the surface of the growth is ulcerated, the needle must be introduced further away and pushed deeper, as there is always an escape of the fluid from the surface of the ulcer. In tongue cancer it is important not to inject through the floor of the ulcer. Such a proceeding may be followed by cellulitis from the introduction of septic matter from the floor of the ulcer along the track of the needle. In cases of enlarged submental glands or epithelioma of the floor of the mouth the injections should be made from the out side.[2]

The objections brought forward against the treatment are then dealt with. Prof. Mosetig-Moorhof affirms that in his experience, and after many hundreds of injections, there is no danger of any coagulation occurring if the drug is injected by accident directly into the blood stream. This clinical experience is supported by Ehrlich's experiments, where it was found that the methylene blue when injected into the bloodvessels of dogs caused no coagulation and no ill effects. This point was further exemplified in a case of very large pulsating soft sarcoma of bone in a child where a profuse rush of blood occurred through the cannula, and where pressure had to be applied after the injection had been made in order to check the bleeding. Here the drug

[1] Wiener Klinik, January, 1892.

[2] Details of cases where the drug was used in malignant disease of various viscera in a somewhat tentative manner, and with no great results, are here omitted, as they do not greatly enhance the value of the paper.

Digitized by Google

must have got into the blood stream. Nevertheless the pain disappeared and the boy felt better.

It has been found that the harder varieties of sarcoma and the carcinomata, especially the former, are likely to derive more benefit from this injection treatment than are the softer, more vascular, and rapidly growing sarcomata. The tumours of the soft parts are likewise more amenable to the treatment than are those of bone. Inflammation never occurs, unless septic material has been introduced with the cannula. Hence the precautions to render the instruments aseptic, and to avoid injecting through ulcerated surfaces. Some œdema may occur soon after injection, and persist for some days. This is probably due to the pressure of the fluid and its slow absorption from the site of injection. Pain is rarely felt for more than a few minutes. It is due to the distension of the parts by the large amount of fluid injected. In some cases it may last an hour or two. In only two cases, where twelve grammes had been injected at one spot, there were some shiverings and a slight rise of temperature.

The benefits are thus enumerated:—1. Relief of pain, usually very marked and often very rapid. This is explained by Ehrlich's observation that in the living subject these dyes are found first of all to affect the nerve endings. This relief of pain after a few injections may be permanent. There is, however, no relief of the distressing pain in case of "carcinome en cuirasse." 2. Improvement of general health. The relief of pain leads to natural sleep, improved appetite, and gain in weight. 3. Mental improvement. It cheers and lightens a patient's end by exciting hopes and rousing him from hopeless despondency. 4. Improvement in function of various organs—e.g., the tongue may become movable in epithelioma linguæ &c. 5. Shrinking of the tumour. Even in the softest and most rapidly growing tumours some retardation of the growth may be produced and perhaps some diminution in bulk. In suitable cases this may be very marked, and may either occur from breaking down of the growth or shrinking up of it. The two processes are usually combined. Secondarily affected glands may shrink as a result of injections into the primary growth. 6. Cicatrisation of a malignant ulcer may occur, especially when the drug is directly applied to the surface. 7. A foul ulcerated surface will clean and fœtor will diminish. It is therefore found in actual practice that shrinking of the growth, and even actual cicatrisation, may be obtained. Sufficient time has not yet elapsed to enable any opinion to be formed as to relapses. Only two out of more than seventy cases treated by Professor Mosetig-Moorhof have up to the present time (one year from the beginning of the treatment) relapsed. The treatment should only, of course, be used in cases that are beyond the reach of operation. It cannot do harm, and may do much good. As an example of the good results to be obtained, there is appended a table of ten cases out of seventy or more treated by Professor Mosetig-Moorhof.

TEN CASES OF MALIGNANT NEOPLASMS TREATED BY ANILINE DYES.

No.	Age and sex.	Nature of tumour.	Duration of disease.	Duration of treatment.	Number of injections.	Amount of methyl violet solution.	Result.
1	Female, aged 66	Myeloid of lower jaw	1 year	7 months	84	230 grammes	Tumour disappeared, leaving shell of bone. No return in 8 months.
2	Male, aged 65	Subperitoneal pelvic sarcoma	1½ ,,	6 ,,	22	66 ,,	Reduced to one-third its original size. Stationary 8 months.
3	Female, aged 32	Supramammary sarcoma	4 years	3 ,,	67	201 ,,	Reduced to half its size. Treatment interrupted by pregnancy.
4	Male, aged 45	Sarcoma of neck	3 ,,	6 ,,	73	219 ,,	About one-fifth of size. Lost pain. Cicatrisation of ulcer. Under treatment still.
5	Female, aged 65	Epithelioma of cheek and eyelid	2 ,,	1 month	21	21 ,,	Almost entirely cicatrised. Small spot left. Under occasional treatment still.
6	Female, aged 47	Epithelioma of nose and eyelid.	10 ,,	8 months	46	70 ,,	Disappearance and complete cicatrisation of ulcer. Local recurrence.
7	Female, aged 68	Carcinoma fibrosum of breast and axillary glands	2 ,,	4 ,,	30	96 ,,	Reduced by one-half. Still swelling of glands. Cicatrix of ulcer up to small spot.
8	Male, aged 45	Epithelioma of tongue and glands	8 months	6 ,,	96	96 ,,	Partial cicatrisation. Glands stationary. Tongue movable.
9	Male, aged 60	Epithelioma of palate and cheek	1 year	4 ,,	125	125 ,,	Reduced to one-third its size. Improved health.
10	Female, aged 38	Carcinoma vaginæ recurrent after amputation of uterus	4 years	3½ ,,	40	40 ,,	Shrinking and cicatrisation of ulcerated parts. Death 7 months later from cancer of pelvis.

Weymouth-street, W.

A COMPLICATED CASE OF FRACTURES OF LOWER LIMB, TREATED BY A MODIFICATION OF THE DOUBLE INCLINED PLANE.

BY R. E. INGRAM-JOHNSON, L.S.A.

I WAS called on Feb. 19th, 1891, to an accident at the Morrison Pit of the South Moor Colliery Company. It was stated that several tons of coal had "come away" and fallen on a man, smashing his leg "all to pieces." He had been brought to the surface when I arrived, and the limb had been partially straightened and put on straight splints by some "first aid" men, who had also applied a tourniquet over the middle of the thigh. On examination I found there was a compound comminuted fracture of both tibia and fibula, the tibia about the middle third for about three inches being broken into fragments. The wound admitted of the finger being easily passed in so as to remove one or two loose pieces of bone. There was a second wound extending from just below the knee along the internal border of the tibia downwards for about four inches, and then curving backwards to about the middle line of the back of the leg. This formed a large muscular flap which was turned over backwards. I washed this wound well with 1 in 20 carbolic lotion, brought the edges together with sutures passing deeply through the muscles, and dressed with iodoform. There was some hæmorrhage from the wound communicating with the fracture, so I plugged it with iodoform wool and dusted iodoform on the top. There were two fractures of the femur, one just above the condyles, and another (oblique) at the junction of the middle with the upper third of the shaft. I found a small punctured wound over the upper fracture, but I did not probe it, so cannot say whether it communicated with the fracture or not. The pelvic region and perineum were much bruised and lacerated, there being a great amount of ecchymosis, so that the catheter had to be passed for four days. The left leg was bruised, and there was a wound across the patella exposing the bone. I found that the ordinary Liston's splint would be useless, as there was so much injury to the leg, and as the perineum was too severely bruised to admit of the use of a perineal band; so after putting the thigh up in a temporary box-splint and the leg on a back splint with foot piece, I gave orders at once for a modification of the double inclined plane to be made for me. This consisted of a double inclined plane made of two boards, each twelve inches wide, one extending from underneath the buttocks to the knee, and the other from the knee to four inches below the foot.

Digitized by Google

In the thigh piece were four slots, two on either side, sixteen inches apart on the outer side, and ten inches apart on the inner side, and two straight splints, one for the outer side to extend the whole length of the thigh piece, and one for the inner side to reach from just below the perineum to the knee. These were each four inches wide, and each provided with iron bolts with screw ends, to work in the slots, so that they might be moved backwards and forwards towards the middle line, so as to fix the thigh when it was brought into position. These bolts were to be secured underneath by winged nuts. In the lower portion of the inclined plane was a foot piece, moving in a slot longitudinally; this was fixed by a nut underneath, which held it perpendicularly as regards the plane. There were also two triangular pieces cut out of the board, leaving a piece in the middle the shape of the leg from two inches below the knee to where the heel would be when the leg was in position. To apply the apparatus, which was done on Feb. 20th, I removed the splints from the thigh piece, padded it, and slipped it under the limb. The femur was then brought into position, and held there whilst I applied the side splints and fixed them. I then put on a straight splint over the top of the thigh, to prevent any upward displacement and bandaged all together. The next thing was to fix the foot to the foot piece; this was done and traction put on the leg till the fracture was reduced and the foot piece was then fixed, and the ankle and leg up to just below the wound were firmly bandaged to the apparatus. The dressings were then applied to the wounds and the limb left undisturbed, except that from time to time the side splints were tightened and the top splint removed to allow of inspection of the fractures.—March 23rd: Removed apparatus, and gave a stimulating liniment to rub the thigh and knee.—25th: Began slight passive movement of knee.—April 6th: Encased thigh in plaster-of-Paris.—10th: Patient was able to move about the house with crutches and left foot in a sling. Large wound almost healed.—May 18th: Removed plaster-of-Paris case.

The patient is now able to walk long distances with only a stick for support. His injured leg is not quite an inch shorter than the other, although several small pieces of necrosed bone have come away from the tibia, and there is still more to come. There is remarkably little necrosis considering the comminution at the seat of fracture. The patient is a man of twenty-four years of age, and of splendid physique. The width of the splint and the position in which the foot piece can be fixed upon it, I claim, has prevented the possibility of any eversion of the foot, and the two triangular spaces on either side of the leg allow of the application of dressings &c. with no pain to the patient or risk of disturbing the fractures. The side splints at the thigh effectually prevent any sideways displacement, and, if combined with a splint at the top, close the limb, as it were, in a box, and prevent any movement of the bone in any direction. Another advantage is that they are easy to tighten or remove. Their removal can be accomplished without any movement of the limb.

South Moor, near Chester-le-Street.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

NOTE ON THE EFFECTS OF INFLUENZA UPON THE MIDDLE EAR.

BY SIR WILLIAM DALBY, F.R.C.S.,
CONSULTING AURAL SURGEON TO ST. GEORGE'S HOSPITAL.

AMONGST the various ulterior effects which the influenza has left upon its subjects it might have been expected that the tract of mucous membrane which lines the middle ear would have been included with tolerable frequency; and although this has in a measure proved to be true, it has occurred in a manner somewhat different from what might have been anticipated. It is true that a certain number of persons during the high temperature stage have for the first time in their lives been attacked with acute inflammation of the middle ear, ending in a few hours with perforation of the tympanic membrane, but these cases, so far as my experience goes, have been comparatively rare; equally rare, it seems to me, have been cases in which persons with ears that have always been healthy have become affected with non-purulent catarrh of the middle ear, combined with obstruction of the Eustachian tubes. I have (in common no doubt with other surgeons) been called to some cases where rapid and acute inflammation of the middle ear has taken place, and to some in which septicæmia has shortly followed, but such instances form a very small proportion to the considerable numbers whom I have observed to be affected in a different manner. These have been confined chiefly to those persons who are and have been for many years the subjects of perforations. There are a good many people who, having perforations, have learned under treatment so successfully to manage them by the use of an absorbent cotton pad that they hear fairly well, and have so minute a quantity of discharge as to be barely noticeable, and in this way continue for many years in a very comfortable condition in respect of hearing and local inconvenience. Many of this class, after an attack of influenza, come back again complaining of further loss in hearing power and greatly increased discharge, which has proved intractable to ordinary measures. The pads have ceased to have their accustomed effect on the hearing for the whole day, and now, in consequence partly of getting soaked with discharge, they are useless. But beyond this the congested condition of the tympanic cavity of itself dulls the hearing so much that the ordinary results of pressure on the stapes are gone for the time. Again, there are many subjects of perforations in whom the cavity of the tympanum has ceased to secrete purulent matter, a condition of a perforation which may be described as dry, and which often remains so for many years. I have observed many of these to resume their previous activity in regard to discharge after an attack of influenza, although for long periods, notwithstanding ordinary colds and exposure to all sorts of variations in climate, they have continued healthy. Thus a person with healthy ears has little to dread from influenza so far as this mucous surface is concerned, but it may become a serious trouble to one whose ears have formerly been the seat of inflammation.

Savile-row, W.

CASE OF HEPATIC ABSCESS.

BY JOHN MCMUNN, L.R.C.S.I., &c.

A SOLDIER, aged thirty-three, of moderate drinking habits, had served six years in the army, two of them in Bengal. He had ague in 1888. While coming through Suez early in November, 1890, his appetite failed. He arrived at Aldershot on the 19th of the same month. Then his eyes looked yellow and his urine was high coloured. On Dec. 1st he became impatient at the hospital, but was discharged in a week. At the time of his discharge he complained of epigastric pain. There was no history of sweats or rigors. When I saw the patient on Jan. 2nd, 1891, he weighed 8½ st., his height being 5 ft. 5½ in. He was worn-looking, anæmic, and slightly jaundiced, with weak pulse, normal temperature, clean tongue, regular bowels, and slight cough. The urine was strongly acid, sp. gr. 1020, clear, plentiful, fragrant, and free from sugar and albumen. He complained of his stomach. There was an epigastric tumour, solid, firm, smooth, rounded, fixed, visible, in diameter three inches, slightly tender, and scarcely moving with respiration. Treatment: quinine, nitro-muriatic acid, and rest. Jan. 10th: Temperature (2 P.M.) 99°; pulse 96.—18th: Doubtful deep fluctuation.—21st: Temperature (2 P.M.) 97·8°; pulse 96.—22nd: Temperature (2 P.M.) 97·8°; pulse 96. The tumour was explored with a needle and afterwards freely opened. Four ounces of thick chocolate-coloured pus escaped. A drainage-tube was inserted, and the whole covered with linseed poultice moistened with carbolic oil. Temperature (6 P.M.) 101°; at 9 P.M. it was normal.—23rd: Sweated a little last night.—26th: Evening temperature 101°. Headache.—27th: Evening temperature 100·5°.—28th: Abundant discharge, which seems to come from a superficial cavity, with an upward inclination from opening. A painful and tender cord runs from the edge of the liver to the umbilicus.—Feb. 3rd: Discharge not so free.—5th: Temperature (6 P.M.) 99°. Headache. Patient not so well.—8th: Tumour, which had gradually shrunk, more prominent, coincidently with decreasing

Digitized by Google

discharge; evening temperature normal. A probe was allowed to ferret its way through softened tissue for about two inches backwards, suddenly it dropped into a large cavity, and pus welled up in abundance, the passage was enlarged with dressing forceps, and this second cavity drained and dressed with carbolic oil.—18th: Since last date syringed through drainage-tube with Condy's fluid; tube expelled from a shallow dimpled recess representing the wound.—24th: Patient joined regiment October, 1891, in the best of health.

The total amount of matter expelled was about three pints.

Gloucester-road, N.W.

NOMA AS A COMPLICATION OF ENTERIC FEVER.

By JOHN DONALD, M.A., M.B.

As noma is a rare complication of this disease, a few remarks on two cases in which it occurred may prove interesting.

On Sept. 9th, 1891, I began to attend two children, Lizzie B——, aged four, and Jane B——, aged eight, both of whom were found to be suffering from enteric fever. They had been ailing for about a week, Lizzie B—— having been taken ill a day or two before her sister. The symptoms all through were much alike in the two cases, the nervous symptoms predominating. There was marked prostration, and great restlessness and delirium of a low type. The temperature varied from 102·5° to 104°, and the pulse ranged from 110 to 130. Diarrhœa was present in both, but persisted longer, and was with difficulty controlled in the elder. No rash could be found in either case, and there were no lung complications. The tongue was dry and cracked, and there were abundant sordes on the lips and teeth. About Sept. 13th the pulse became very weak, and there was a tendency to heart failure. This was combated with stimulants, given freely in the form of diluted brandy; but it was with difficulty that they were roused from their lethargic condition to partake of this and other necessary nourishment. With the persistence of such a low "typhoid" state, the prognosis was very bad, and when noma set in their recovery was practically hopeless. On Sept. 16th a hard swelling was felt in the right cheek of the younger, which gradually increased in size and got tense and glazed externally. Ulceration took place internally, but the disease did not follow the rapid course that sometimes occurs. The child remained in a comatose condition till Sept. 20th, when she died, before perforation of the cheek had taken place. On Sept. 18th noma was found in the right cheek of the elder girl, and pursued a similar course, till she died, in the same comatose condition, on Sept. 22nd.

Noma as a rule follows on some debilitating disease, but for its development the presence of foul air and bad sanitary arrangements are usually regarded as essential. Here the conditions were present, as the cases occurred in a small, badly ventilated house in a narrow street. In another case, which I saw during convalescence from measles, where a fatal issue likewise took place, the house was permeated with bad smells. It is probable that the micro-organisms supposed to cause this disease gain entrance to the tissues locally, as it is difficult to conceive how they should select such a site, if they were introduced into the circulation in the first place. In the cases of enteric fever referred to it is easy to comprehend that the state of the mucous membrane of the mouth was such as to furnish a suitable spot for the inroad of disease germs. In regard to local treatment, no violent measures were resorted to, as the low, practically hopeless condition of the patients did not seem to warrant any such. So much of the ulcerated tissue as could be scraped easily away was removed, and antiseptic washes were freely employed to cleanse the mouth.

Glasgow.

AN UNUSUAL CASE OF TWINS.

By GEORGE JOHN O'REILLY, L.K.Q.C.P.I., &c.

I ATTENDED Mrs. K—— on the 8th ult. in her fourth confinement. There was nothing unusual to note in the history of this pregnancy, except that she complained of not having felt the movements of the child for some ten days before delivery. During the labour I felt satisfied that I noticed the movements of the fœtus during examination. When delivery was effected an eight months' embryo presented itself in a macerated condition, the cuticle peeling off in several places. When I grasped the uterus to express the placenta I noticed that organ was larger than usual after delivery, and that the surface was lumpy and uneven. I examined per vaginam, but could not detect anything abnormal. I gave a dose of ergot and waited results. Labour pains soon set in, and became stronger every minute, and on again examining I found the head of a second fœtus presenting. After a short time a living child was expelled, and as it was very feeble I had it wrapped in cotton wool, and kept near the fire. The placenta came away within a short time. There was little or no hæmorrhage. The case terminated normally. The mother made a good recovery and was up on the eleventh day. I hardly expected the child to live, and did not weigh it at birth. However, the infant has lived, and takes its nourishment well, and seems to thrive. On the twenty-first day it weighed with cotton wool and shawl 3 lb. 1 oz. A week afterwards it weighed 3 lb. 5 oz. There was only one placenta; the cords of both were attached within a short distance of each other; two-thirds of the placenta were of a livid red colour and of firm consistence, and to this portion the firstborn was attached. The cord was three times as thick as that of the living child, the other one-third portion of placenta was healthy. There was a distinct line of demarcation between the two portions. The stillborn child was unfortunately not weighed, but I should say it was from 4 to 5 lb.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Prœmium.

SEAMEN'S HOSPITAL, GREENWICH.

NOTES OF TWO FATAL CASES OF INFLUENZA.

(Under the care of Dr. JOHN ANDERSON, C.I.E.)

THESE two cases are specially interesting, as showing the mode of death in cases of influenza which are not fatal in consequence of bronchitis, pneumonia, or some other similar complications. Both patients died from syncope due to cardiac failure induced by the influenza alone, and in both no cardiac lesion, either of the walls or of the valves, existed. In the second case the histological examination, showing that the heart structure was quite normal, was made by Mr. Hewlett, M.B. Lond., Demonstrator of Bacteriology in King's College. For the report of these cases we are indebted to Dr. M. H. Spencer.

CASE 1.—A. C——, a sailor, aged thirty-five, was admitted into the hospital on Jan. 11th, 1892. He was taken ill eleven days before admission with pains "all over him," accompanied by some cough, but had not kept his bed. When he was admitted the temperature was 101·6°; respiration 42; pulse 118. Auscultation revealed only sibilant rhonchus over the greater part of the lungs, with some small râles, most marked over the left lower lobe. No impairment of resonance anywhere over the lungs. The heart sounds were normal. The urine was free from albumen. There was a good deal of cough, with profuse watery expectoration. Ammonia mixture ordered every two hours. For the next two days the patient remained in much the same condition, the temperature still continuing high, ranging between 102·4° and 103·4° at night, and falling to between 99° and 100° in the morning. The dyspnœa, however, had diminished. At midnight on Jan. 14th the pulse for the first time showed signs of failure. Stimulant was freely given, and quinine and digitalis were ordered. On the 15th his condition was much worse. The pulse was 140, and although the bronchial signs over the lungs had diminished

Digitized by Google

in intensity, he was attacked with urgent paroxysmal dyspnœa, each attack threatening to prove fatal. The expectoration was still profuse and watery. On the following day the dyspnœa had become more constant and was extreme; the countenance was dusky, and there was no improvement in the condition of the pulse. Temperature 103·2°. During the night there was slight hæmoptysis, followed soon after by loss of consciousness, the patient lapsing into a condition of coma, and dying early on the morning of the 19th.

Necropsy.—The body was well nourished. On opening the thorax, both lungs were found to be enormously distended throughout their entire bulk. On the right side the liver was pushed down by the lung, so that its free edge nearly reached the umbilicus. The pulmonary tissue, on section, was greyish and dry; there was no œdema. The heart was natural in appearance except for some thickening of the coronary arteries. The cardiac muscle looked healthy, and there was no dilatation of the ventricles. No evidence of disease was discovered in the other organs.

CASE 2.—E. P——, aged forty-eight, a sailor, was admitted to the hospital on Jan. 19th, 1892. The patient had been ill for six days before admission. His illness began with a shivering fit, which was followed by some cough, which had been increasing lately. During the two days before admission he had been suffering much from pains in the head and back. On admission, his complexion was very dusky. The lungs were resonant all over, the breath sounds were somewhat harsh over the upper lobes in front, and over the right base there were crepitant râles; the tongue was furred; the urine was loaded with urates, and contained a trace of albumen. Temperature 101°. After rising to 103° the temperature on the 21st dropped suddenly to normal, and with this fall of temperature the patient's condition seemed to improve considerably. He progressed favourably until the 27th, when a sudden change for the worse took place in his condition. He was suddenly attacked in the night with oppressive and urgent dyspnœa; the face became livid, and he was to all appearances dying. He rallied, however, after the administration of stimulants. Ether and ammonia with digitalis were given every two hours, and brandy was taken freely. On the next day the pulse, which had showed every sign of failure, had improved, and there was no urgent dyspnœa. Over the lungs there were still crepitant râles and rhonchi at the bases, but no fresh signs. Up to the morning of the 30th this temporary improvement continued, but at 1 P.M. he was again suddenly attacked with urgent dyspnœa; this time the heart showed rapid signs of failure, and the pulse soon became imperceptible at the wrist. There was no improvement after an injection of twenty minims of ether, and he died in about five minutes after the onset of the paroxysm.

Necropsy.—The right lung was pretty generally adherent from old pleurisy. The left was free. There was considerable congestion of both lower lobes, and some œdema of the right upper lobes, but no consolidation. The heart was flabby in appearance, and on its surface there was a rather unusual amount of fat deposited. There was no valvular disease save for some thickening and opacity of the posterior mitral cusp; no mitral or aortic incompetence. Heart muscle: Histologically this was found to be perfectly healthy; striation well marked. There were no traces of either fatty or fibroid degeneration. It was specially stained for micro organisms, but none were seen. The liver was enlarged and fatty, and the spleen enlarged and soft. The other organs, including the brain, were healthy in appearance.

STROUD GENERAL HOSPITAL.

AMPUTATION AT THE HIP-JOINT.—LIGATURE OF THE FEMORAL.—OPERATION FOR COMPOUND FRACTURE OF THE PATELLA.

(Under the care of Mr. STORRY.)

ALTHOUGH these three cases from the Stroud General Hospital present no exceptional features, the results of treatment have been so satisfactory that they are well worth recording. The first case of sarcoma of the femur shows the result of amputation at the hip-joint by the method of Furneaux Jordan, and the advantages of that method; it is, however, too soon to say that there is no likelihood of the appearance of secondary growths. Cases 2 and 3 are notable for the aseptic course of the wounds after operation; this is more especially remarkable in Case 3, where the wound had been inflicted before the man applied for treatment. There is no more satisfactory result of such an injury known to us. For the notes of the cases we are indebted to Mr. A. W. Waller, house surgeon.

CASE 1.—E. W——, tailoress, aged twenty-three, a fairly healthy-looking girl, was admitted into Stroud Hospital on Sept. 24th, 1891, suffering from a tumour at the lower end of the right femur. Her family history was good; both parents were alive and healthy, and no phthisis, syphilis, or malignant disease could be traced in any near relative. Previously she had always enjoyed good health, and had never had any serious malady. In June she first noticed a small swelling at the inner side of the lower end of the right femur, which caused some pain and stiffness on walking, but not at other times. It slowly increased in size, and in August she consulted a medical man, and was given a course of iodide of potassium, the leg being kept at rest on a back splint, and subsequently put into a plaster-of-Paris case. No benefit was obtained by these means and the tumour continued to enlarge until Sept. 24th, when she presented herself at the hospital for treatment. At that time a rounded tumour could be felt situated on the inner condyle of the right femur and occupying an area rather larger than a crown piece. The skin and soft parts were normal and freely movable over it, but the tumour itself was fixed, its outline ill-defined, and it had an elastic semi-fluctuating feel. On deep pressure it was painful, but there was no elevation of temperature and the glands in the groin were neither enlarged nor tender. There was some effusion into the knee-joint, and movement of it caused pain. No organic disease was present, and the urine was free from albumen. Palliative treatment was tried for three weeks, but during that time the tumour very rapidly increased in size until it attained a bulk about as big as half a cricket-ball. As it was evidently a new growth, it was thought desirable to ascertain its pathological characters before operating, so the patient was anæsthetised and a small portion removed for microscopic examination. It proved to be a mixed, small round-celled and spindle celled sarcoma. Amputation at the hip-joint was then advised. Some delay was caused by the reluctance of the patient and her friends to consent to this procedure, and it was not until a week later that she was placed on the operation table, and then suppuration had taken place in the incision, causing the temperature to rise on the previous day to 102°. Ether was the anæsthetic used, and a slight modification of Mr. Furneaux Jordan's method of amputation employed. The limb was rendered bloodless with an elastic bandage and an Esmarch's tourniquet passed round the thigh, as high up as possible, beginning from the front, crossed at the back, the two ends brought up on either side, again crossed over the groin, and then passed round the hips, crossed at back, and hooked in front. A short circular flap of skin and fascia was raised, everything divided down to the bone, and the limb rapidly sawn off about five inches below the great trochanter. The femorals and all other vessels that could be seen were ligatured and the tourniquet removed, but practically no hæmorrhage occurred at this stage of the operation. An incision was next carried up outer side of the stump to a point about midway between the crest of the ilium and the great trochanter, the muscles stripped off, and the rest of the femur extracted by opening and cutting round the capsule. A few vessels spouted, but were at once secured and very little blood was lost. At this time the patient became rather collapsed from the shock, and the pulse was rapid and feeble, but it soon improved after an enema of brandy. The flaps were sutured with silver wire, two large drainage-tubes inserted, and the stump dressed with iodoform gauze and carbolised wool. The patient was removed to bed covered with hot blankets and surrounded with hot water bottles, stimulants being given both by the mouth and rectum. She soon recovered from the anæsthetic without vomiting, but did not rally from the shock for some time, and three hours afterwards her temperature was two degrees (Fahrenheit) below normal. During the night she was restless, but took some nourishment, and on the following morning her temperature had risen to 100·6°, and she was free from pain. On the third day after the operation the temperature rose to

Digitized by Google

103°; the discharge soaked through the dressings, so they were removed and the stump redressed. It was looking remarkably well and free from inflammation. On the sixth day it was again dressed; the flaps were found to be uniting well, but there was still a considerable amount of discharge, and a little pus oozed from one point. For the next month it continued to progress favourably, and all healed with the exception of a short sinus which formed at the outer corner of the stump, and continued to discharge. She, however, gradually regained her strength, and a week before leaving hospital was able, with assistance, to attempt to get about on crutches. On Dec. 9th, seven weeks after the operation, she was discharged. She has since been under supervision, and has made almost uninterrupted progress. Lately, however, she has at times complained of rather severe paroxysms of occipital headache lasting for an hour or so, and occasionally accompanied by vomiting, but she has no optic neuritis, and the attacks do not seem to affect her general health. The stump is healthy, the cicatrix firm, and remains soundly healed. With the aid of iron and cod-liver oil she is putting on flesh, appears brighter, and is, to some extent, able to resume her old occupation as a tailoress.

CASE 2.—J. P——, aged forty-seven, a contractor, was admitted into Stroud Hospital suffering from an aneurysm of the left popliteal artery. He was a stoutly built, healthy looking man, but inclined to be plethoric. He gave a good family history, none of his relatives having suffered from any hereditary disease. His own health had always been good with the exception of an occasional attack of gout. There was no history of syphilis. He stated that two months previously to admission he had strained his knee in lifting a sack, and this had been followed by pain and stiffness in the joint for about a month, after which he noticed a swelling at the back of the knee, which gradually increased in size. On admission, on July 22nd, 1890, all the signs of a sacculated popliteal aneurysm were well marked. The left popliteal space was occupied by a circumscribed ovoid tumour about the size of a hen's egg, pulsating with an expansile impulse, immediately checked by pressure on the femoral artery. There was no thrill over it, but a soft bruit could be heard on auscultation. The knee was semi-flexed and movement painful and limited. There was also slight œdema around the ankle. The posterior tibial artery could be felt pulsating, but not the anterior. There were no signs of an aneurysm anywhere else, and the radials appeared to be normal and free from atheroma. The other organs were healthy, and there was no albumen in the urine. As sufficient assistance for continued pressure on the femoral was not obtainable, it was decided to ligature the femoral artery. This was done on July 23rd. The artery was exposed at the apex of Scarpa's triangle by the usual incision, a No 3 chromicised catgut ligature passed round it through a small opening in its sheath, and firmly tied. A drainage-tube was inserted, the wound closed, stitched with silver wire and dressed antiseptically; the whole limb was then enveloped in cotton-wool. All pulsation in the sac was immediately arrested and its size slightly diminished. After the operation the limb became cold and the foot rather dark coloured, but in about three hours it began to lose its lividity, to feel warmer, and regain its normal appearance. Next day the sac felt firmer, and was entirely free from all pulsation. The tibial arteries could not be felt, but the limb was warm, though slightly œdematous. There was very little pain, but there was a feeling of numbness and tingling. During the next few days the leg, and especially the foot, became very painful, necessitating the use of hypodermic injections of morphia. The sac remained free from the slightest pulsation, and was perceptibly contracted and consolidated. No pulse could be detected in either of the tibials at the ankle. At the end of a fortnight the operation wound had united by first intention, and was entirely healed. The pain had ceased; all œdema had subsided, but the limb remained stiff and weak. On Aug. 18th the patient left the hospital. The aneurysmal sac was then very much diminished in size, was hard, the limb could be moved without pain, and the patient could bear some weight on it. He was provided with crutches, and not allowed to put the foot to the ground. In August last, thirteen months after the artery was ligatured, he was again seen and examined. No sign of the aneurysm could be felt in the popliteal space, nor could any pulsation be detected in either of the tibial arteries. The movements of the leg were perfect. The man complained of occasional numbness and pain about the instep, which at times even kept him awake at night, but otherwise he was as well as ever, and was able to attend to his business without the slightest inconvenience.

CASE 3.—H. H——, aged twenty-eight, a timber hauler, was assisting to move some timber on March 31st, 1890, when he slipped and fell, falling with his right knee, which was flexed, upon the edge of a triangular iron instrument called a "scraper," used for scraping the bark from timber. On admission to the hospital a few hours after the accident the following condition of the joint was found. There was a transverse wound about three inches long running across the patella, cutting directly down to the bone and completely opening up the knee-joint. The patella was fractured into three pieces. The upper fragment consisted of nearly half the patella itself, the lower part of the bone was divided into two fragments, one small piece of bone was lying almost loose, separated from the surrounding tissues, whilst the other fragment and larger portion was still attached to the ligamentum patellæ. The patient was immediately put under ether, when Mr. Storry enlarged the incision transversely right and left, removed altogether the smaller loose portion of the lower half of the patella, and, having cleaned and cut off some sharp corners of bone, sutured the remaining upper and lower fragments with two wire sutures, leaving the ends long and outside the skin wound. The portions of bone came into excellent position, but left a small gap where the loose portion had been removed. Two openings were made into the joint on either side of the patella, and drainage-tubes inserted. The joint was well syringed out with (1 in 20) carbolic solution, while the skin wound was brought accurately together with catgut sutures and dressed with iodoform and boracic wool, and the limb placed on a McIntyre's splint. There is nothing much to record after the operation, the temperature never rose above 100° F., and the joint was dressed for the first time four days after the operation, when the drainage-tubes were removed. The leg was dressed once a week for the next fortnight. Subsequently, when an attempt was made to unwind and withdraw the wire sutures from the patella, the wire in each case broke off short close to the bone, and was consequently left alone. The limb was put up in a plaster-of-Paris casing, and the patient was allowed out of bed with crutches six weeks after the operation. In November, 1890, eight months after the operation, the patient was examined by Mr. Storry, who found the knee-joint perfectly useful. Absolute bony union had occurred, and scarcely a ridge could be felt where the bone had become united. The man had been at work for a month, and declared he could use the joint as well as ever, and had felt no inconvenience from the wire sutures which were left in the patella. In February, 1891, he was again seen, when he was doing his old work of timber hauling, the movements of the joint remained perfect, and he could even kneel on it without any discomfort.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Discussion on Phagocytosis and Immunity.

AT the meeting of the Society on the 16th inst. the PRESIDENT introduced the subject in a few words. The discussion was to show how the blood dealt with morbid material introduced into it. He then called upon Professor SIMS WOODHEAD, who in his address said that the phagocyte theory was closely associated either with "chemiotaxis" or the humoral theory. The latter appeared to be in direct opposition to Metchnikoff's theory, though there was an attempt now being made at a reconciliation and combination of the two. At present he was in favour of the theory of phagocytosis. Metchnikoff and Buchner must be regarded as the leaders of the two sides in this controversy, though the result of their work was now being corroborated or disproved by others. Metchnikoff's view was that amœboid cells, in contact with micro-organisms, retained their activity

Digitized by Google

and function, whilst the incorporated germs died and disintegrated. Many leucocytes appeared to have lost this power; but as a primitive function of protoplasm it was capable of being stimulated into action when required. Although so much stress had been laid on leucocytes at first, it had been shown later that not all the cells concerned were true leucocytes, but were fixed tissue cells deprived of their processes and occupied by a large nucleus. These were the microphages or final phagocytes, and were far more active and aggressive than the macrophages or leucocytes. Their ordinary function was to remove useless effete matter, but they appeared to combine together in the performance of the more difficult task of attacking living organisms. The amœboid cells were limited largely to the removal of innocuous material, organic or inorganic, which was a different form of the phagocytic function. It had been shown that the mesoderm cells in sponge were capable of attacking and digesting a living organism like leptothrix, and it was assumed that the scavengering power still remained, but that the attacking power had been lost by disuse. Tissue resistance meant power of reaction of its cells, and cells, which in the first instance would be destroyed by invading bacteria, might by acclimatisation acquire the power of resisting them. He then referred to Metchnikoff's original experiments with the Daphnia and the mode of absorption of the Monospora bicuspidata, and proceeded to discuss the question of erysipelas, in which it was alleged that the streptococci were outside the zone of leucocytes, so that if the cells played any part it must have been in removing dead organisms killed by the fluid extruded. With regard to this, he would say that "what was sauce for the goose was sauce for the gander," and there was no more evidence for this mode of destruction than for digestion in the first instance by the cells. Recently Metchnikoff laid more stress on the action of fixed cells. Anthrax bacilli had been demonstrated within leucocytes, stained by aniline dyes. Inasmuch as bacilli stain when dead, this was no evidence of their ingestion, whilst living; but Metchnikoff had shown that vegetable germs retained the power of reproduction by isolating three such cells with the contained organisms and obtaining a pure culture. Although thoroughly degenerated bacilli did not take the stain, in some cases, where cells were breaking down owing to the bacilli being numerous and getting the upper hand, the organisms stained perfectly. In Frank's experiment on rats one only died out of twenty-two; the bacillus anthracis was killed *in situ*, being localised by the density of the tissue and the congregation of leucocytes. The idea of chemiotaxis was originally suggested by botanists. Experiments showed that deleterious materials were avoided, whilst nutrient ones were taken up and inert ones were not regarded; but after a time the cells became accustomed to the first variety and approached them. Metchnikoff stated that similar phases occurred in the body, and that with the gradual increase of poison its paralysing effect was not produced, and it was treated as inert matter. In opposition to this, Emmerich and Mattei suggested the presence of an anti-biotic fluid constituting the products of bacteria. They afterwards receded from this, and attributed its production to the cells of the host. This condition of "acclimatisation" Buchner pointed out might be maintained, but was usually soon lost. This process of chemotaxis and getting rid of devitalised microbes he looked upon as the cause of recovery and acquirement of immunity in acute germ disease. There were instances where the same substance in different degrees of dilution either attracted or repelled cells, and it was shown by Schultz that yeast was actually more active in *dilute* solutions of corrosive sublimate, iodine, or carbolic acid than in simple solutions. To demonstrate the difference in action between fluids and cells of the body upon micro-organisms pathogenic organisms were enclosed in paper or pith envelopes and inserted under the skin of animals. Under these conditions growth and development continued within, whilst the animal, though susceptible, did not suffer from the specific disease. Here fluids had free access, the cells alone being excluded. These processes, however, could not be considered the sole factors. It would seem as though the reacting and congregating leucocytes constituted the first line of defence, the epithelium of the capillaries and lymph tracts the second, and when these were broken through the animal system lay at the mercy of the invading germs. It had been suggested that by breaking up the leucocytes some bactericidal material might be set free, as was suggested by the action of quinine in certain diseases; but on experiment it was found that animals inoculated after treatment in this way died sooner than the "controls," and it was concluded that active leucocytes exerted the more powerful resistance. Diphtheria and tetanus were instances of toxæmia due to development of bacteria in unhealthy areas of the system or their introduction in large numbers, and could be resisted by destroying the bacteria before this toxine could be produced in sufficient quantity to give rise to the characteristic symptoms. Immunity could be established by the system becoming accustomed to small doses of the poison. It was an extremely difficult thing to account for special immunities for the several diseases. Many theories had been proposed and disposed of without a satisfactory explanation being arrived at.

Dr. BURDON SANDERSON declared that he was an opponent of the theory of phagocytosis, and said that he would endeavour to place before the Society the difficulties that he and those who thought with him had in accepting the theory. He would only touch the question of the action of the leucocytes. The facts themselves were not in dispute, but the interpretation of them might, he thought, be found without ascribing to leucocytes any other than their known physiological properties; whereas those who believed in phagocytosis allowed to leucocytes an extraordinary power which was not in accordance with the accepted principles of biology. An organism as a whole, such as a human being, had a certain power of recovering from injuries and of resisting micro-organisms, which might reasonably be termed a specific power. All were agreed that on the invasion of the organism by an exciting cause of disease leucocytes collected at the point of entry. Those who believed in phagocytosis attributed this to a specific power of the leucocyte to counteract the particular disease, and not to their ordinary physiological properties. These latter were essentially three: (1) Amœboid movements; (2) the power of incorporating solid particles; and (3) their subjection to a kind of allurement or repulsion which many substances had over them, known as "chemiotaxis." Whenever an injury happened to the body, provided it was of moderate intensity and capable of producing ordinary inflammation, a migration of leucocytes towards the injured spot set in. The explanation was that so long as the surroundings were normal the leucocytes remained quiescent, but that as soon as a devitalisation of any part occurred, a flow of leucocytes from the normal to the abnormal part set in, and that this was a physiological process was shown from the fact that it occurred during the absorption of a tadpole's tail. As the movements of leucocytes were independent of the nervous system, it would be as reasonable to attribute to the tadpole's leucocytes an appreciation of the advantage which would accrue to the frog from an absorption of its tadpole tail as it was to ascribe to the leucocytes the wonderful specific power of acting differently to the various specific infections.

Professor KLEIN admitted his inability to accept the arguments advanced by the supporters of the phagocyte theory, and in support of his position he stated that the question of phagocytosis embraced a very much wider field of observation than was included in the views already advanced. Some investigators included all instances in which bacteria were found engulphed in cells. This, he contended, was the first error, and illustrated his remark by exhibiting a number of photo-micrographs showing a dozen instances of micro-organisms contained in cells which were breaking down under their influence, thus reversing the process described. He said that the influence of chemiotaxis, as shown in the cells of bile-ducts in which psorosperms were growing, was of quite a different nature to that asserted. In the many cases of immunity in which inoculation was not followed by disease, were the bacilli killed by leucocytes or some other agent, or by the two in combination? He referred to the experiment of Emmerich and Mattei, in which it was shown that the micrococcus of swine erysipelas, which would kill a rabbit when injected subcutaneously, did not do so when introduced into the circulation; and further, that an animal so treated acquired immunity from infectability by subsequent inoculation, and that phagocytes cannot then be found at its site. Reference was made also to the observation of Metchnikoff—that after forty-eight hours living bacilli can still be found in the blood of an immune animal; but it was stated that in such cases there

Digitized by Google

was not a commensurate number of cells containing the micro-organisms. In the dog, cat, and rat, which were insusceptible, it was extremely difficult to find any adequate number of bacillus-bearing cells after inoculation. In the next place, he would ask if there were any well-established cases in which bacilli were known to have been destroyed by lymph or other juices—and here he alluded to experiments being carried out by Dr. Frederick Andrewes, and which showed that pus already dead, and even when twenty-four hours out of the body, had a rapidly noxious effect upon these organisms. When anthrax was introduced into the dorsal lymph sac of a frog hours elapsed before any bacilli were seen enclosed in cells, the lymph itself being capable of destroying them. Professor Klein then gave an account of some experiments, in which it was found that a rapid diminution in bacilli occurred within two hours of their introduction into the body, which was not at all in accordance with the time observed in their gradual approach and engulfment by cells. He thought it was much simpler to assume that the juices of the body were germicidal, though Buchner's explanation gives little account of what takes place with regard to the bacilli after they are weakened by exposure to them, as to whether they are then taken up and carried away by cells, acting as scavengers. That important part of the cell's duty had yet to be proved.

Mr. KANTHACK said the question at issue was "whether immunity from infective diseases or lesions was caused by phagocytosis—that is, through the phagocytes alone and through nothing else." The chief points are: I. The influence of the body fluids; II. Chemiotaxis; III. Phagocytosis. I. Do the living fluids of the body play no part in the production of immunity? The serum of many animals has a marked bactericidal power outside the body, but we cannot establish any general law, because there is no necessary correlation between the natural insusceptibility of an animal to a disease and the bactericidal power of its serum over the microbe causing such disease. This has been put forward as a grave objection to the so-called humoral theory. But he thought wrongly, for it is impossible to draw any logical inference as to the artificial causation of immunity by contrasting a naturally immune animal with a naturally susceptible one. In future, experiments should be made in such a manner that the bactericidal power of the serum of a naturally susceptible animal be tested (*a*) before it has been immunised, and (*b*) after it has been artificially immunised. If, then, any law can be established, we must expect to find one or more of three conditions—namely, after the acquisition of immunity the serum should be (1) either more bactericidal, (2) or possess greater attenuating powers, (3) or possess greater destructive power over the toxines of the microbes. It is too narrow to judge by the bactericidal power alone, for it is impossible to disconnect the bacteria from their metabolic products, and it is these which cause the disease. As long as the poison is not neutralised, it matters not whether the bacilli are eventually killed or not. To give examples, we find—(1) Under the first heading that (*a*) the serum of a guinea-pig after artificial immunisation kills the vibrio Metchnikovi; (*b*) the serum of a guinea-pig after immunisation has greater bactericidal power over the bacillus Chauvœi. As an exception, we may mention the serum of a sheep protected against anthrax. But, on the other hand, Christmas succeeded in extracting from the organs of an immunised rabbit a substance which had greater destructive power over the anthrax bacillus than a substance similarly extracted from the organs of a rabbit not protected against anthrax. According to Bouchard, it has been proved for nine infective processes that the serum of the immunised animal has greater bactericidal power than the serum of the same animal in the non-immunised condition. These are anthrax, charbon symptomatique, cholera, erysipelas, diphtheria, tetanus, pneumonia, and the lesions caused by the vibrio Metchnikovi and the bacillus pyocyaneus. (2) Under the second heading we find that (*a*) the serum of an immunised rabbit attenuates the streptococcus of erysipelas; (*b*) the serum of an immunised rabbit attenuates the bacillus pyocyaneus. (3) Finally, under the third heading, we find that (*a*) the serum of an immunised animal neutralises the tetanus toxine; (*b* and *c*) the same has been asserted with regard to the toxines of diphtheria and pneumonia. (1) Those who object to test-tube experiments as being artificial do not hesitate to use little paper bags filled with germs, and place them under the skin of refractory or immunised animals. Such experiments are as little natural as test-tube researches, for (*a*) we thus localise the process by artificial means; (*b*) the fluid which passes through the paper may be of an inflammmatory nature, and is not necessarily the same as the normal body fluids. In studying the artificial production of immunity, the absolute followers of Metchnikoff are prone to neglect the most important part in the causation of infective diseases and lesions—namely, the chemical products of the microbes which undoubtedly cause the phenomena of such diseases. (*a*) We find that an animal made immune against a living microbe can also resist the toxine of such microbe to varying degrees. Examples are tetanus, pneumonia, diphtheria, vibrio Metchnikovi, pyocyaneus, charbon symptomatique, and others. (*b*) *Vice versâ*, an animal made immune against the toxine also resists the living microbe. Therefore the processes responsible for these results must assumedly be the same. Now immunity against toxines cannot in any way whatever be explained by means of phagocytosis. He concludes, therefore, that at the present state of knowledge it is impossible to assert that the living plasma (or body fluids) are of no consequence. 2. Chemiotaxis has of late been introduced as a welcome support to the phagocytic theory. Certain chemical substances, according to their degree of concentration, attract or repel the phagocytes, but if the phagocytes are in a medium already containing these chemical substances, equally distributed, they will not be attracted on adding more of these substances unless they be added in a highly concentrated condition. Analysing this, we have three possible cases:—(*a*) The metabolic products of the microbe are present in equal quantity in the tissues and at the seat of lesion, therefore no migration of phagocytes can take place. (*b*) If the degree of concentration is higher at the seat of lesion, we shall have a migration of phagocytes thereto. (*c*) If the degree of concentration is higher in the blood, the phagocytes may migrate back into the blood. This teaches us nothing as to the acquisition of immunity, for (1) if true, it is simply a statement of concomitant facts; (2) on such a view our successes in the production of immunity become merely a matter of chance and good fortune; (3) it supposes, without the slightest foundation, that in an animal immunised against a microbe, the toxine of such microbe circulates in its vessels; and, lastly, it neglects the fact that, besides diapedesis, we have, as a rule, hand in hand with positive chemiotaxis, a great general increase of phagocytes and leucocytes, depending of necessity on a stimulation not of the leucocytes and phagocytes, but of the elements giving birth to these bodies. Hertwig, in his monograph, sums up this theory in the following manner: "(*a*) In an immunised organism the negative chemiotaxis, which the body exhibited before being made immune, has been replaced by a chemiotaxis behaving positively towards the specific virus." If so, we ask, Why and how? We are also told that "the effects of the metabolic products of microbes show themselves as positive and negative chemiotropism and also as acquired irritability (Reiznachwirkung). The existence of positive chemiotropism explains the localisation of the virus through the attraction of leucocytes and subsequent phagocytosis. The existence of negative chemiotropism explains the possibility of a general infection by means of a diffusion of the micro-organisms. By means of suitable injections of bacillary products a negative may be changed into a positive chemiotaxis, and thus a cure be effected." This is mystical and unsatisfactory, and treats of the body as though it were a specimen on the microscopic slide. 1. By causing fever artificially in a susceptible animal, two or three hours after the temperature has begun to rise considerably there is a very great increase of leucocytes, not only of the so-called lympho-cytes, but also of the larger elements, and this leucocytosis persists for more than twelve hours. On inoculating the animal when in this conditi on with anthrax it will die just as usual; yet here the army of phagocytes was increased at least tenfold. 2. Thus the increased number of phagocytes *per se* is not sufficient. They require also the special training. And here we come to the most unsatisfactory part of the theory. Before an animal is immunised the phagocytes are more or less inert against a particular microbe, but as soon as ever a relative immunity is established they are extremely voracious. We must ask, why does phagocytosis appear now or why are the cells suddenly enabled to destroy what previously perhaps killed them? 3. The occurrence and importance of vaccine fever during

Digitized by Google

the process of immunisation points to more general changes than a mere change of habit of the phagocyte alone. 4. That changes occur in all the tissues has been shown by Emmerich, who succeeded in protecting animals by inoculating them with the tissue juices of such as had been immunised. 5. Some of the methods of immunisation, as the injection of so-called antitoxine, or of small repeated doses of poison, &c., point strongly to general changes in the body, the phagocytes being altered with the rest of the body. 6. Lastly, phagocytosis does by no means explain many of the phenomena mentioned in the first part of the discourse.

MEDICAL SOCIETY OF LONDON.

On the Cure or Subsidence of Ascites due to Hepatic Disease.—Hæmatemesis, with Special Reference to that Form met with in Females in Early Adult Life.

AN ordinary meeting of this Society was held on Feb. 15th, the President, Dr. Douglas Powell, in the chair.

Dr. J. S. BRISTOWE read a paper on the Cure or Subsidence of Ascites due to Hepatic Disease. He took as his text four cases which were under observation up to the present time. 1. A governess, aged forty-four, who came to St. Thomas's Hospital in the summer of 1886. She was depressed and lacrymose, and suffered from delirium and hallucinations. She had jaundice, ascites, œdema of the legs, and diarrhœa; also suffering from bronchitis and an attack of poly-arthritis during her stay of nine months and a half. There was no albuminuria and no enlargement of veins. Five, thirty-two, and thirty-four pints of fluid were removed by paracentesis abdominis on three several occasions, and she left greatly improved on May 24th, 1887. She was again admitted on Aug. 29th, 1889. Her complexion was sallow, she still had bronchitis, and eighteen and twenty pints of fluid were removed from the abdomen. She left on Jan. 12th, 1890, and has continued well since except for the bronchitis. She was seen last week. The case was a typical one of chronic alcoholism, as was borne out by the mental condition, and an attack of peripheral neuritis on the second occasion, and it may be accepted that the ascites was due to cirrhosis of the liver which still existed, and was liable to induce a recurrence of the ascites. 2. A gentleman aged thirty-five who had fallen into intemperate and immoral habits in 1878. He was lost sight of till Oct. 8th, 1882; he was then weak and thin, suffered from sickness, and for three weeks had had œdema of the feet and ascites. On Nov. 20th he was worse, was irritable and rambling, and had in addition some fluid in the left pleura. On Nov. 22nd he was admitted to St. Thomas's Home, with jaundice and dyspnœa, the left pleural and the peritoneal cavities being full of fluid. A month later he was improved in all respects. Three pints of fluid had been removed from the pleura, and he left on Jan. 24th, 1883, for New Zealand, where he has remained in fairly good health. Here, again, was a very clear alcoholic history; and though the ascites got well without tapping, there could be no doubt, from the fact of the development of this form of dropsy and of jaundice, that his liver was at that time affected with early cirrhosis. 3. A man in good circumstances, aged forty, who kept an eating-house. He was known to drink many glasses of spirits daily, and was seen in consultation on Oct. 24th, 1888. His complexion for some time had been sallow, and for six weeks there had been enlargement of the abdomen and œdema of the legs. In addition the liver was enlarged and there was jaundice. He was enjoined to abstain from alcohol, to take a tonic and a pill of mercury digitalis and squill. He was tapped five times; nine, thirteen and a half, nineteen and a half, nineteen, and fifteen pints being removed. On Dec. 28th the liver was smaller, and he had gained flesh; four tappings were performed since, the quantity of fluid removed being eight to sixteen pints, the last occasion being in August, 1889. After that he went to Vichy, and on his return took cold and was laid up with bronchitis and pleurisy. He was tapped again on Feb. 5th and March 3rd, and twice since, and has been taking 1-16th of a grain of iodine off and on. On Feb. 8th, 1892, he was in excellent health and spirits, and carried on his business with his old energy, going to market three times a week, but he continued to take gin-and-water. In this case paracentesis was performed fourteen times in the course of a year and ten months, the alcoholic history was indisputable, and that the ascites depended upon the hepatic disease is shown both by the enlargement of the liver and the temporary jaundice. 4. A lady, aged twenty-four, belonging to a respectable and wealthy family, with small and delicate physique, and usually enjoying good health, was seen April 30th, 1890. At the end of the preceding year she had a sudden and profuse attack of hæmatemesis while abroad; there was a recurrence on arriving at a seaport in England, and since reaching home there had been two more, the last on the day preceding the consultation. Latterly there had been pain and uneasiness after food, with loss of appetite. She was anæmic and weak, and was treated for the ensuing twelve days as a case of simple ulcer of the stomach, with great improvement. The abdomen then filled rapidly in three days. Eleven pints were removed on May 15th, and by the 28th paracentesis had been performed three times, nine pints being withdrawn on each occasion. The liver was now found to be enlarged. The general health had improved, and the gastric symptoms had disappeared. After another tapping a small nodule could be felt, and the idea of cancer was entertained. In June she was tapped four times, the quantity removed being from four to fifteen pints. It was then found out that a brother had been under treatment for a congenital syphilitic affection of the eye. This led to the diagnosis of syphilis, and iodide of potassium was prescribed in ten-grain doses. Later the quantity was increased and mercury was added. In August she was tapped four times, and in September thrice, the quantity being from four to seven pints. Altogether paracentesis was performed twenty-seven times, the last occasion being Sept. 22nd, 1890. She was now better than she had been for years. The causes of obstruction were threefold: 1. True cirrhosis affecting the small vessels and capillaries. 2. Cancerous and syphilitic growths occupying the transverse fissure compressing or involving the portal trunk, and occlusion by thrombi. 3. Obstructive disease of the heart or lungs causing "nutmeg" liver. The first three cases belonged to the first and the fourth to the second class. With regard to the mode of recovery in these cases, it was, in the first place, amply proved that there is a fairly free communication between the portal vein and the systemic veins, and hence when portal obstruction exists there is a tendency for the blood of the portal circulation to be shunted into some of these other veins which gradually dilate, so that without any beneficial change in the liver itself the ascites may disappear. The œsophagus, as shown by Drs. Wilson and Radcliff, has a ring of veins which is largely concerned in the process, and the consequent varicose condition of the submucous veins in this part and their tendency to rupture are the source of the profuse hæmoptysis and melæna in the late stages, though the vessels of the stomach and duodenum are the ones affected at first. Sometimes, however, there is no evidence that the anastomosing veins have dilated, and on this supposition alone recurrence of ascites after renewal of bad habits would be inexplicable. Moreover, in the case of a chronic inflammatory process dependent on an irritant locally applied, cessation of the influence would be likely to be followed not only by arrest of the disease, but also by some amelioration in so much of it as had recently occurred and was amenable to treatment. In the first three cases there was jaundice, which implied a wider or profounder change than that producing ascites, and which subsided. Again, as in Case 4, there are causes of obstruction which are removable. The efficacy of treatment depends largely on the accuracy of diagnosis. Doubtless there are many cases of visceral syphilis which are misinterpreted to the detriment of the patient. A simple and fairly successful treatment is to promote the general health by suitable diet and tonics, to cut off alcohol, to tap from time to time without waiting for extreme distension, and to regulate the bowels. Bearing in mind the tendency to spontaneous diarrhœa, purgative measures were not to be recommended, and diaphoretics were of little use; more was to be hoped for from diuretics, especially copaiba in ten-grain doses and the pill of mercury, digitalis, and squill. There was no objection to the use of mercury and iodide of potassium in the early stages.—The PRESIDENT, referring to œdema of the legs, said he should be inclined to attribute it rather to the general condition of the heart and circulation, and he thought that rest and deprivation of alcohol was to some extent answerable for the improvement that took place under treatment, apart from local considerations.—Dr. HAVILAND HALL suggested

Digitized by Google

that repeated tapping was liable to produce peritonitis and adhesions, thus introducing fresh areas for absorption and collateral circulation, and cited an illustrative case. He referred to some of the drugs recommended for cirrhosis. — Dr. HADDEN mentioned a necropsy recently made on a man who fourteen years before had been a patient with cirrhosis hepatis and ascites under Dr. Murchison, and was tapped. The cirrhosis was well marked, but there was no ascites, and death was due to other causes.—Mr. MARMADUKE SHEILD, referring to paracentesis, said that great care was needed to ensure absolute cleanliness of the instruments, and that the fluid should be evacuated slowly through a fine trochar. He thought the very rapid dropsy in the fourth case suggested thrombosis. The presence of retinitis or choroiditis afforded the best indication of congenital syphilis.—Sir HUGH BEEVOR mentioned a case in which great œdema of the legs occurred in an alcoholic subject, there being nothing to explain it. In another case of cirrhosis the gradual dilatation of veins on the right side of the abdomen was obvious to the sight.—Dr. SIDNEY PHILLIPS mentioned a case not syphilitic, which cleared up under iodide of potassium, and he thought this a good drug to give in cirrhosis hepatis, in doses up to forty grains, three times a day.—Dr. PASTEUR, referring to the ascites of young children, said that many of them were doubtless due to tubercle, and cleared up.—Dr. BRISTOWE, in reply, said he regarded œdema of the legs as due to the collection of fluid in the pelvis and pressure on veins there. He mentioned other cases similar to those quoted, but of which the notes were less complete. He thought the examination of the eyes was of great value in recognising syphilis, but said that the signs were so slight as to have been overlooked by skilled observers. In young children tubercle, alcoholic cirrhosis, and congenital syphilis had to be considered in the production of ascites.

Dr. DONALD HOOD read a paper on the Hæmatemesis of Early Adult Life in Females. The author wished to draw attention to the clinical phenomena accompanying this form of hæmorrhage, stating that from his own experience of the symptom he would feel inclined, in a large majority of instances, to look upon it as but denoting a state of passive congestion, or stasis in the vessels of the stomach, and as being directly due to the anæmic condition so generally found accompanying this form of hæmorrhage, and not necessarily the result of ulceration. His personal experience is confined to about forty cases, and as supplemental to these he brought before the Society 155 cases collected for him by Dr. Goodall, late Medical Registrar to Guy's Hospital, from the clinical and pathological records of that hospital during a period of twenty years. It was noted that during that period no case is recorded at Guy's Hospital of a young girl succumbing to an attack of hæmatemesis due to gastric ulcer. During the same period of twenty years sixteen patients were admitted suffering from a fatal peritonitis, the result of a perforating ulcer. Eight were men and eight were women. Ulcer of the stomach, regarded as causal in producing fatal peritonitis, is equally fatal to both sexes, and at much the same time of life. It was asked why it should not be equally causal with regard to hæmorrhage; clinically severe hæmorrhage, excepting as the result of incipient cirrhosis, being markedly rare among males in early life. In discussing the etiology of hæmatemesis, cases would appear to fall into one of three fairly well-defined groups—the period of early adult life, largely composed of anæmic girls, and comprising the cases referred to by the author; the period of middle life, in which the hæmorrhage is usually due to cirrhosis or ulceration, hæmorrhage from cirrhosis being much more frequent among the female sex than is supposed to be the case; and, lastly, the period of advanced life, in which malignant disease and ulceration are about equally met with. In the course of the communication reference was made to two cases published by the late Dr. Murchison, in which a minute pore-like orifice was found leading into a bloodvessel. In both of these repeated attacks of hæmatemesis occurred before death. Hæmatemesis is so frequently found accompanying the anæmia of girl life that it would appear to be one of the results of that profound blood change, and when the gastric symptoms of anæmia are compared carefully with those due to ulceration of the stomach, a marked difference will usually be found to exist, the stomach symptoms of anæmia being generally of less intensity. The author considered the matter as one of importance, having special regard to treatment, for he maintained that in a very large majority of cases of hæmatemesis occurring in early adult female life and complicated with anæmia, a treatment based on saline aperients combined with iron will give better results than one which would be urgently demanded if an ulcer of the stomach were the source of hæmorrhage.—Dr. HABERSHON acknowledged that these cases did not afford proofs by post-mortem examination, and referred to the long experience of Dr. Brinton and of the late Dr. Habershon, which left the impression in their minds that actual ulceration did occur, though it was often no doubt superficial. In many cases the hæmatemesis appeared to occur at what would be the menstrual period in girls suffering from anæmia and amenorrhœa.—Dr. SIDNEY PHILLIPS pointed out that the two main points were (1) the occurrence of gastric ulcer without hæmatemesis, and (2) (?) the occurrence of hæmatemesis without gastric ulcer. He mentioned cases in men and women in whom sudden hæmatemesis had caused death, and no lesion had been discovered post mortem. Some cases of hæmatemesis were associated with violent pulsation of the aorta, pain and vomiting, and hypochondriasis.—The PRESIDENT alluded to cases which had proved fatal and in which no lesion had been discovered post mortem. He referred to a specimen in the Middlesex Hospital museum in which a minute aneurysm had ruptured, and suggested this as a possible cause. He noticed that patients usually got well rapidly after the occurrence of hæmorrhage, possibly through the clot affording some protection to the site.—Dr. HOOD, in reply, mentioned two patients in whom there had been no hæmatemesis, but in whom a large number of healed ulcers were found in the stomach after death. He remarked on the wonderful rapidity of recovery after hæmorrhage. His plan of treatment was to give nothing by the mouth for two days, then small doses of opium, feeding by enemata.

CLINICAL SOCIETY OF LONDON.

Perforation of the Vermiform Appendix.—Acute Appendicitis.—Relapsing Appendicitis.

AN ordinary meeting of the Society was held on Friday, Feb. 12th, the President, Sir Dyce Duckworth, in the chair.

Dr. D. B. LEES read notes of four cases of Perforation of the Vermiform Appendix. Case 1: A man aged twenty-seven was admitted into St. Mary's Hospital on Oct. 17th, 1890, with a history of having caught cold on the 15th, followed the next morning by pain in the right iliac fossa, which came on gradually. The bowels had been regular, but he had vomited. There was moderate distension of the abdomen, with some tenderness over the appendix. He diagnosed a lesion of the appendix, but in view of the mildness of the symptoms did not deem it necessary to interfere. In twenty-four hours, however, the man was in a hopeless condition. At 9 P.M. he began to vomit, the matter being at first dark green and then black, and he died six hours later—less than four days from the onset of the attack. Post mortem the appendix was seen to be perforated at the tip, and contained concretions. A section of one of the larger concretions showed a white nucleus enveloped in white stratified layers. It was evident that the concretions had formed within the appendix and had been there some time previously to the illness. Case 2: A lad aged seventeen was admitted on Nov. 22nd, 1890. He had been seized with a sudden sharp pain in the right iliac region on the 20th. It grew worse, and he vomited. The abdomen was moderately distended, tympanitic all over, and tender on pressure. No lump could be felt. Dr. Lees called in Mr. Page, and some hours later the appendix was cut down upon and found to be perforated, outside which a concretion was seen. There was some local peritonitis. A ligature was placed round the appendix, and the distal part removed. There was a direct communication between the perforated appendix and the peritoneal cavity. He made a perfect recovery. Case 3: A man aged twenty was admitted on Jan. 3rd, 1892. Early on that day he had been seized with an acute pain, at first referred to the umbilicus, but ultimately settling down in the region of the vermiform appendix. Vomiting began two days later, and the bowels were so loose that he was sent into the hospital with a diagnosis of typhoid fever. He was

Digitized by Google

evidently suffering from peritonitis, for the abdomen was swollen, especially on the right side. It was very tender on pressure, and some tumefaction could be made out in that region. Mr. Silcock was called upon to operate, and made an incision two inches long over the right linea semilunaris. When the peritoneum was opened the cæcum came into view with a deeply congested piece of omentum adherent to it. This piece was taken away, upon which some pus escaped, but the appendix could not be seen. By careful search, however, it was discovered behind the cæcum and closely adherent to the parts around. The appendix was then seen to be ruptured in two places, and it was accordingly ligatured and removed, and the man made a good recovery. Case 4: A man aged seventeen or eighteen was admitted on Feb. 5th, 1892. Three days previously, while waiting at table, he had been suddenly seized with a sharp pain in the abdomen, followed by vomiting. There was a distinct swelling above the middle of Poupart's ligament on the right side, which was painful and very tender. A deep seated, tense swelling was made out by careful manipulation. The same evening Mr. Page operated, and immediately the peritoneum was opened there was a flow of pus with a strong fæcal odour. The appendix was felt in the neighbourhood of the wound, but was so firmly adherent to the parts around that it was impossible to remove it or even to ascertain whether there was a perforation or not. Beyond it the abscess was cut off from the general peritoneal cavity by strong adhesions. The abscess was therefore washed out, a drainage-tube inserted, and the wound closed, and since that time the progress of the patient had been perfectly satisfactory. On the fifth day a small concretion came out of the wound the size of a grain of wheat. Dr. Lees pointed out that all these cases were essentially of the same nature, and it was curious to remark that they all occurred in persons of the same sex and at about the same age. He asked what explanation could be given of this fact. The cases showed that perforation of the appendix did not necessarily give rise to collapse, and the symptoms might be so mild as not to suggest the necessity for an operation.

Mr. PAGE recorded a case of Appendicitis where operation and removal of the Appendix were performed after the symptoms had lasted without intermission for twelve weeks. There was a large swelling in the iliac fossa, the thigh was acutely flexed, and the man was extremely ill. The abdomen was opened by incision as for iliac ligature, and the appendix, swollen and rigidly distended, was found with much difficulty embedded in a mass of adherent omentum. It was removed a quarter of an inch from the cæcum after the application of a proximal ligature. No fluctuation being felt in the iliac subperitoneal swelling, it was not opened, but a few days after the wound had healed by first intention pus began to flow from the track of the drainage-tube. For many weeks there was profuse burrowing suppuration, and the man's life was in great danger, but he was ultimately discharged well, and has been at work in good health since. The case was recorded as an instance of subperitoneal suppuration, and to illustrate the dangers which may arise in cases where there has not been perforation, and the cause of the appendicitis has been other than concretion. Although by no means suggesting that operation and removal of the appendix are to be carried out in all cases, for many no doubt recovered without surgical interference, the author nevertheless advocated early operation in cases where the symptoms were severe, and where a distinct iliac swelling was to be felt. There were no means of determining the precise nature or of predicting the course of any case, and the character and grade of the symptoms had to be the measure of the need for operation. The presence of active inflammation was certainly no bar to it in the early and acute stage. Cases of "relapsing" appendicitis, in which of course a period of quiescence would be chosen as the time of operation, are destined in all probability to become much less common than they were. The operation itself was probably much easier in the early stage than when the parts were firmly matted together by adhesions, and there was then also less risk to the patient than is entailed by delay and the chances of suppuration. In support of this he referred to cases operated on by McBurney, Stimson, and others in the early acute stage, and to a case of his own, to be described with Dr. Lees', where a perforated appendix was removed on the third day with the best possible results. It was desirable to examine all cases having acute intra-abdominal symptoms under an anæsthetic, for where the general condition and history were suggestive of appendicitis, the presence of a distinct iliac swelling would be a great help to the surgeon in deciding as to the propriety of operation.

Mr. PAGE next read a short account of a case of Relapsing Appendicitis. The history was that of a medical student who had had several attacks of appendicitis in the course of five years, and who was submitted to operation during a period of quiescence after an acute attack in October last. The abdomen was opened by an iliac incision, and the appendix was found sharply kinked, distended with mucus, and its walls much thickened, but there were no signs of concretion or ulceration. It was bound by adhesions to the cæcum throughout its whole length and to neighbouring coils of intestine by firm adhesions. An uninterrupted recovery followed the removal of the appendix, and the patient has remained free from discomfort up to the present time. It appeared that in this case there had been no other cause than kink to account for the attacks, and nothing short of an operation could possibly have freed the patient from the risk of their recurrence.

Mr. PAGET read notes of an unusual case of Sloughing of the Vermiform Appendix. The patient was a man of twenty-five, who had never had any sort of trouble with his bowels. An acute abscess formed round the cæcum, and when Mr. Paget opened it the vermiform appendix floated out with the pus. No foreign body or concretion was found at the operation or afterwards in the dressings. The appendix had sloughed off at its base; it had a pinhole perforation at its free end.

The PRESIDENT remarked that the term "typhlitis" appeared to have been replaced by "appendicitis," a word which might be American, but was certainly not English. He would undertake to say that it would not appear in the nomenclature of diseases now in course of compilation by the Royal College of Physicians nor in the Transactions of the Society. He urged that there must be many causes of tumefaction in the ileum unassociated with disease of the appendix, such, for example, as local inflammation of the caput coli, for which a purge was an effectual remedy. He inquired of Dr. Lees how he recognised "tenderness over the appendix." Many cases of the sort arose, he believed, from catarrh of the appendix, which might be determined by cold. From the condition of catarrh to the formation of concretions was but a step. Post mortem a very large number of appendices were found to contain concretions.—Mr. FREDERICK TREVES considered that the shortness of the mesentery to the appendix favoured its folding over and forming a band, and thus conducing to concretion formation. These concretions were neither foreign bodies nor fæcal matter, and as a matter of fact there were some cases in which, though there was some local induration, no concretion could be found. Many acute cases terminated favourably, and no general rule for operating could be laid down, each having to be considered on its own merits. He protested against the desperate hurry displayed in America in dealing with these cases. In one or two cases of his own in which operation had been refused the patients recovered without it. If operation became general, some lives might be saved, but certainly many patients would be subjected to operation without actual necessity. The results in recent cases showed the deaths to be about 1 in 50. Recovery had taken place after one or many attacks with almost complete obliteration of the appendix. After an attack of inflammation swelling at the site of the cæcum indicated persistent inflammation, and was an indication for operation. In others pain referred to the labium or scrotum or the bladder was important. He recommended that the incision should be made at what was known as McBurney's point, two inches internal to the anterior superior spine of the ileum, as it was safer to approach the appendix from outside and behind the cæcum. Ventral hernia was specially liable to ensue, but was less liable to follow when there was inflammation and a tube was used. As a further precaution he allowed a month to elapse before the patient was allowed to get up.—Dr. DYSON (Folkestone) mentioned two cases in which, after mild symptoms lasting three days, there were sudden collapse and death; both occurred in boys; there were sickness and tenderness, but no local swelling. He mentioned a similar case in the practice of a colleague. The advisability of operating was considered in all, but in two was negatived, and in the third the operation proved unsuccessful. Post mortem all had suppurative peritonitis

Digitized by Google

following perforation of the appendix with a concretion. He asked what guide there was to operation in such cases. From personal experience he was not disposed to agree with Mr. Page as to the necessity of operating in recurrent cases.—Mr. SILCOCK quoted a case in which he had operated recently. His incision was a little to the outer side of the linea semilunaris; he came upon the cæcum immediately.—Mr. BRUCE CLARKE reported the case of a woman who, after a blow on her side, was found after an interval of forty-eight hours to have a local spreading peritonitis. He determined to cut down without delay, adopting the incision referred to. The distended cæcum was readily found, but the appendix had sloughed off, and was found in the pelvis with a concretion in the lumen at the orifice. There was a large aperture in the colon, but recovery was complete. He thought there was more difficulty in deciding as to operation in chronic than in acute cases.—Dr. LEES said that in the cases reported there was no yielding of the scar. The concretions were often true calculi.—Mr. PAGE agreed as to the yielding of the scar after rapid healing. He congratulated the College of Physicians upon their intention of getting rid of the term "appendicitis," and he thought the term "caput coli" might follow.

EPIDEMIOLOGICAL SOCIETY.

A MEETING of this Society was held on Jan. 20th, Dr. E. O. Hopwood in the chair.

Brigade-Surgeon R. PRINGLE, M.D., read a paper in which he proposed to answer the question: What is efficient vaccination? It was, he maintained, such a system as conferred an immunity against small-pox equal to that acquired by a previous attack, which rendered revaccination superfluous, and the isolation of the sick in hospitals, except for their better treatment, needless. He disputed the value of the cicatrices as a test of success; for though a good cicatrix was positive evidence, so many accidents might interfere with the course of the successive stages in the development of the vesicles that after a normal incubation and papulation—which distinguished true vaccination from mere local irritation, and which were best observed from the third to the fifth days—had been passed through, a scar might be left from which nothing could be learned. He denied the existence of any direct ratio between the number of insertions and the degree of protection conferred; for when, as he had often seen in the Himalayas, some fifty men had been inoculated with the same variolous lymph by a single insertion over a space the size of a sixpence, and in the same place, the resulting eruption differed in every case, showing their dependence on individual susceptibilities under an identical mode of procedure. Dr. Pringle strenuously asserted the non-necessity of revaccination, which he had refused to practise during his thirty years of Indian service. He had been in consequence a marked man, but after his retirement he had his reward in the unwilling testimony borne to the success of the method by a hostile department when a special commission was appointed to inquire into the astonishing immunity from small-pox enjoyed by his districts at a time that the mortality in the North-west Provinces generally was awful—viz., in the epidemic of 1883-4. At first they were disposed to doubt the correctness of the returns, but they ended by ascribing the exemption from small-pox solely to the system of arm-to-arm vaccination he had carried on uninterruptedly for the twenty years from 1864. He quoted a remarkable passage from an ancient Hindu work, which showed that true vaccination was known and practised in India centuries before the birth of Jenner: "The small-pox produced *from the udder of the cow* will be of the same mild nature as the original disease. ..... the pock should be of a good colour, filled with a *clear* liquid, and surrounded by a circle of red. ..... There will be only a slight fever of one, two, or three days but no fear need be entertained of small-pox so long as life endures." Pasteur's attentuation of virus by successive cultures has been applied in India for hundreds of years to inoculations with variolous lymph, which the document in question directed to be taken from "the most favourable cases," and he had seen series of such selected inoculations in which there was no general eruption, and the local phenomena were scarcely distinguishable from those of vaccination.

Dr. WILLOUGHBY heartily agreed with Dr. Pringle as to the objectionable method of collecting the mixture of sanio-purulent and foreign matters supplied as calf lymph from the vaccine department of the Local Government Board, which he only used when it was demanded by parents, and he deplored the appalling amount of what passed as vaccination among general practitioners and the public, but when put to the test proved a delusion and a snare. But he could not concur in deprecating the practice of revaccination. Granting that it was needless, even if practicable, when the primary operation was really perfect, and that its successful performance was evidence of that having been imperfect, what stronger argument could one have in favour of continuing it until all vaccinators had attained to Dr. Pringle's ideal? One need but look to Germany, which up to the year 1874 was in much the same condition as England as regards vaccination, but had suffered heavily from the epidemic of small-pox in 1871-2, imported by French prisoners and carried by French refugees into other countries. The absolute exemption enjoyed by the population of Frankfurt at a time when the prisoners massed there were being decimated was rightly ascribed to the compulsory revaccination of every child at the end of its school life, which had been in force for more than a generation; and one of the first acts of the Imperial Parliament was to extend it to the whole empire. Since that, Germany had enjoyed an absolute immunity from epidemics, while the deaths in Prague had been 650, and in Vienna as many as 900 in a single year. Indeed, analyses of the cases reported throughout the empire showed that for some time past they had been exclusively among foreigners recently arrived, or the disease had been contracted from them by Germans who, born before 1860, had escaped the operation of the present law, and infants not yet vaccinated.

Dr. COPEMAN entirely agreed with Dr. Willoughby on the value and purpose of statements as to number and area. Some authoritative directions there must be; the public vaccinators followed the official regulations, while many private practitioners made one small insertion in order to indulge the prejudices of ignorant parents, and it was almost wholly among these unfortunate children that cases of post-vaccinal small-pox occurred. The analogy of all experimental inoculations proved that there was a ratio between the quantity of virus introduced and its effects, though not so absolute with living as with chemical poisons; and the area abraded approximately represented the probable absorption of lymph; but it was especially important in dealing with the children of the poor, whose arms were exposed to every conceivable form of septic infection, that the wounds should be so arranged as to dry and heal as early as possible.—Dr. PRINGLE agreed with Dr. Willoughby as to the superiority of lymph taken at the earliest possible period, at all events before the eighth day, but pointed out that the development of the vesicles depended on the temperature being more rapid in warm weather, and mostly so in children much exposed to the sun and air. In India, as was well known, vaccination could not be successfully performed in the hot season, though small-pox was then most rife, the progress of the vesicles being so unduly accelerated that the normal stages were not gone through.

HUNTERIAN SOCIETY.

A MEETING of the Hunterian Society was held at the London Institution on Jan. 27th, Dr. Stephen Mackenzie, President, in the chair.

Dr. GALLOWAY exhibited a case of Peculiar Disturbances of Sensation, with Muscular Wasting due to Syringomyelia. The details of this case will be found on another page.—Dr. JACKSON concurred in the diagnosis, and to him Dr. Galloway was indebted for permission to exhibit the case.—Dr. STEPHEN MACKENZIE thought the diagnosis was justified, and referred to other cases.—Mr. OPENSHAW asked how the unilateral nature of the symptoms could be explained.—Dr. TURNER remarked that he had seen one case on the post-mortem table, being attracted to examine the cord by the extreme muscular wasting of the subject.—Dr. NEWTON PITT remarked on the unilateral distribution of the symptoms and their slow progress. He had a specimen of the joint affection due, on post-mortem examination, to a glioma of the cord, with distension of the canal.—Dr.

Digitized by Google

GLOVER LYON said he had a case under his care which he had at first taken to be progressive muscular atrophy in a young subject. He thought the present case aberrant in that the wasting was not so extreme as the complete loss of power might indicate.—Dr. GALLOWAY replied.

Dr. FRED. J SMITH showed a case of Symmetrical Local Asphyxia The patient, a woman aged forty-five, had noticed the condition for some seven or eight years. The case was of interest in that her father suffered in precisely the same way, indicating the constitutional nature of the malady.—Mr. SYMONDS mentioned a case of a similar nature which he had brought forward some years ago, in which scleroderma was associated with the vascular changes.—Dr. NEWTON PITT said that many conditions were included in local asphyxia, and said that if it were associated with hæmaturia, then quinine was of great value in treatment. He referred to a case of his own, in which syphilis and peripheral neuritis seemed to have an etiological connexion with the asphyxia.—Dr. S. MACKENZIE had seen many cases in which scleroderma was associated with local asphyxia. He had paid much attention to hæmoglobinuria, but had not been fortunate enough to find a single case with local asphyxia in addition.

Mr. C. J. SYMONDS showed a case of Trigeminal Neuralgia affecting the left infra-orbital branch of the nerve. The patient was a middle-aged man, for whom, after all other methods of treatment had been exhausted, Mr. Symonds had excised about one inch and a half of the infra-orbital nerve with immense relief to the patient.

Mr. OPENSHAW showed a case of Subdural Hæmorrhage; trephining; recovery. The patient, aged forty-two, fell and struck his head on Sept. 12th, 1890. For three days he complained only of severe head pain; on the fourth day he became delirious, and on the fifth fits commenced to appear. Mr. Openshaw saw him soon after the fits had begun. From the character of the fits and from the increasing depth of the oncoming coma, Mr. Openshaw was led to diagnose hæmorrhage within the cranial cavity causing pressure. He therefore immediately proceeded to operate. A flap was turned down from the skull, and as no signs of fracture were apparent, a trephine was applied. The dura mater bulged into the trephine hole; it was incised, and five ounces of blood-clot and serum were removed. The patient made an extremely rapid and satisfactory recovery, with the trephined piece of bone growing *in situ*.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

AN ordinary meeting of this Society was held on Jan. 8th, Mr. T. Gunton Alderton, Vice-President, in the chair.

Microscopical sections of Aural Polypi were exhibited by Mr. R. Lake, and pathological specimens by Mr. H. Percy Dunn.

Mr. EDMUND OWEN reported a fatal case of Unrecognised Cervical Caries in a servant girl, who was admitted under his care into St. Mary's Hospital on May 29th, 1891. Until that time she had been treated as an out-patient at a general hospital for "rheumatism." She had pains in every branch of the superficial cervical plexus and in the distribution of the great occipital nerve, and she was very ill. She was at once placed flat on her back, with a small cushion under her neck and big sand-bags on either side. The post-pharyngeal abscess was evacuated, and for a time the girl improved. Pains persisted, however, and she lay constantly with her hands up to her head. After lying about five months in the horizontal position and growing steadily weaker, Cheyne-Stokes respiration set in, and she died on Nov. 11th, 1891. A vertical section of the upper cervical vertebræ and the cord was exhibited, showing disappearance of the transverse atlo-axoid ligament and pressure of the odontoid process against the cord; also suppuration in the neighbourhood of the first four cervical nerves. Mr. Owen remarked on the too frequent mistaking of the neuralgiæ of central spinal disease for "rheumatism," and said that, if an error had to be made, far better was it to mistake rheumatism for spinal disease than spinal disease for rheumatism; for whilst the former error would be more inconvenient than harmful, the latter might not only prove an irremediable calamity, but might well be reckoned a stupid blunder. Discussion followed, in which Drs. W. Hill and Batten, and Messrs. Lunn and Keetley, took part, and Mr. Owen replied.

An ordinary meeting of this Society was held on Friday, Feb. 5th, Dr. Chas. Wells, President, in the chair.

Pathological specimens were shown by Mr. Percy Dunn, and Dr. Campbell Pope exhibited a case of Malignant Disease of Tonsil in a man aged forty.

Mr. HOWARD MARSH read a paper on Some Points in the Operative Treatment of Cancer of the Breast. He alluded first to the earliest age at which the disease is met with. Last year he had under his care an unmarried female, thirty years of age, with carcinoma of the left breast, which, in spite of operation, ran its fatal course in nine months. Similar cases at the ages of twenty-seven, twenty-three, and twenty-one had been recorded, and Sir J. Paget had told him that he had seen one in a girl aged nineteen. They were rare, and very quickly fatal. On the other hand, the author had lately operated on an old lady aged eighty-three, where the operation was successful. He thought the old bore operations favourably. He had also operated during the puerperium without any unfavourable symptoms. The author had been much impressed by the fact that recurrence of carcinoma of the breast seemed to be comparatively early in cases in which the wound healed by primary union, and to be postponed in cases in which the healing of the wound was delayed. He hardly knew how to make use of this observation, except to confirm the practice of freely removing the gland and skin, and laid special stress on the importance of dissecting away all the subglandular areolar tissue and pectoral fascia, as well as, of course, any glands that could be felt in the axilla. The healing of the wound in modern surgery was so rapid that any carcinomatous elements left behind were uninjured, and would soon grow actively. When, however, the condition of the tissues was modified by free suppuration or other disturbing agency, the "cancer elements" that had escaped removal might apparently be destroyed.

Surgeon-Lieut.-Colonel HENDLEY, C.I.E., read a paper on the Indigenous Medical Systems of India, giving his experiences in the native States, in which he had served for more than twenty years. He reviewed the practices of the orthodox Baids (Hindu physicians) and Hakims (Mussulman practitioners), who have absolutely no knowledge of anatomy or physiology, and described the Yunani or Greek humoural system, which is that practised by the Hakims. Surgery was relegated to barbers and quacks, known as jhairahs, in whose hands gangrene from tight bandaging and other atrocities were frequent. To these must be added Sathiyas or Couchers, who operated on the eye with filthy instruments with an alarming percentage of failure. Jain and Sikh priests practice empirically amongst their religious disciples; but the common people rely most on charms, superstitions, ceremonies, fulfilment of vows, and fervent worship at shrines. Quack medicines were sold everywhere, and legislation was imperatively necessary against the sale of secret remedies containing poisons. The confidence of the people was waning, and the European system making great strides. For example, in his own district, Jaipur, with a population of 3,000,000, his major operations in surgery had risen from ninety-seven to 236 per annum in his central hospital in ten years; while in that period in his dispensaries, which had increased from sixteen to twenty seven, upwards of 2000 major and 67,000 minor operations had been performed. Medically also the progress was as marked. Thus in 1890, 170,000 new cases had been seen, against 57,000 in 1881, and in all 1,100,000 new cases had been treated in ten years. In the prevention of disease much was due everywhere to improved sanitation, vaccination, regulation of fairs, &c., and the number of native medical men in private practice was also increasing. In conclusion the author spoke in highest terms of the advantages of the Indian Medical Service.

MANCHESTER PATHOLOGICAL SOCIETY.

THE fourth meeting this winter of the above Society was held at Owens College on Wednesday, Jan. 20th, T. C. Railton, M.D., M.R.C.P., President, in the chair.

Löffler's Diphtheria Bacillus.—Dr. ASHBY showed stained specimens of Löffler's Bacillus of Diphtheria, and also pure test-tube cultivations, which he had obtained through the

Digitized by Google

kindness of Dr. A. Baginsky of Berlin, and drew attention to the fact that the diagnosis of diphtheria by means of the detection of the bacillus in the membranous exudation had now begun to assume some practical shape, and there was a good prospect of the diagnosis being arrived at with certainty in doubtful cases without any great difficulty and with considerable rapidity. The most ready method was to detach a small piece of membrane and place it for five minutes in a 2 per cent. solution of boracic acid, then to draw the piece of membrane along the surface of sterilised blood serum in a test-tube, and maintain it at a temperature of 37° C. for twelve to twenty-four hours. At the end of this time, if the bacilli were present, characteristic small, white, rounded colonies were visible along the tract of inoculation. The bacilli were stained with a pure carbol-fuchsine, and examined with an oil immersion lens. To obtain a pure cultivation a second or third preparation must be made. The bacilli were thicker than the tubercle bacilli, mostly joined together in twos or more, and their ends were darker than the central portions. If an enlarged experience confirmed these observations, a notable advance had been made in the diagnosis of diphtheria.

Rupture of the Heart.—Dr. DIXON MANN exhibited the heart from a case in which rupture of the aorta immediately above the valves had taken place. The patient had three separate attacks of hæmorrhage into the pericardium, manifested by collapse, the last proving fatal. The aorta presented patches of atheroma.—Dr. R. T. WILLIAMSON also showed a specimen where an aneurysm of the left ventricle had burst into the pericardium. The patient had suffered from angina pectoris, and death occurred suddenly. The aneurysm was situated at the posterior surface of the left ventricle, about midway between apex and base. There was marked atheroma of the coronary arteries, but the cardiac muscle appeared normal, except at the seat of the aneurysm.

Tubercular Tumour of the Choroid.—Dr. HILL GRIFFITH showed sections and drawings of a Tubercular Tumour of the Choroid which had burst through the outer side of the globe and formed a prominence the size of a filbert covered by the thinned sclerotic, the rest of the eye being filled with stratified blood-clot. There was total separation of the retina, and the sight was entirely lost. The patient was a boy aged two years, under the care of Dr. Glascott; the eye had been inflamed six weeks, and the bulging had been present one week. Microscopically, numerous caseating centres were found with giant cells and reticulum; no examination for bacilli was made.

Micro-Photographs.—Dr. Harris showed with the aid of the limelight a very beautiful series of micro-photographs, illustrative of the more common diseases of the lungs.

Dr. Railton, Dr. Kelynack, Mr. Roberts, and Mr. Westmacott showed card specimens.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Section of Anatomy and Physiology was held on Jan. 15th, Dr. Brooks in the chair.

Exhibits.—1. Professor FRASER exhibited a beautiful collection of photographic enlargements of serial sections of embryos and of brains. He explained how they were made, and pointed out the great advantages of using this method of reproducing such sections as contrasted with old methods of copying with the camera lucida.—The CHAIRMAN complimented Professor Fraser on his work, and suggested the advisability of supplying with such reproductions line tracings, which would bring the important point of the sections more clearly before the untrained eye.—Professor FRASER, in reply, agreed with the Chairman, and explained how such tracings might be simply and quickly produced with the aid of photography.—2. Professor BIRMINGHAM exhibited a specimen in which the transverse ligament of the atlas was ossified, except at the extremities, which still remained fibrous at the attachments to the bone. The odontoid process could be rotated freely within its ring.—The CHAIRMAN asked some questions about the specimen, to which Professor Birmingham replied.

Papers.—1. Dr. ROBERT H. WOODS read a paper on a few applications of a physical theorem to membranes in the human body in a state of tension. The theorem was that if P be the pressure of fluid contained in a membrane curved circularly in two directions at right angles to one another, and if r_1 and r, the two radii of curvatures, and T the tension at a given point,

$$\text{then } P \propto T \left(\frac{1}{r_1} + \frac{1}{r}\right).$$

This theorem, when applied to the heart, shows that the tension in the walls is not the same for different points on the heart wall, nor can it be constant for the same point in different stages of contraction, on account of the variation in the radii of curvature, but will be greater according as the curvature is more gradual and the heart more dilated. The organ, then, will have to make a greater effort at the beginning than towards the end of systole. But the heart wall is thinnest when most dilated; hence we have the two factors contributing towards the difficulty of commencing systole. The paper went on to show that this difficulty is, in part at least, got over by the columnæ carneæ and musculi papillares which cross the cavity of the heart, and thus act more directly on its wall, as well as economising space. An example was taken from the pathological condition known as prostatic bladder. The ridging on the interior of the bladder was an attempt to form columnæ carneæ of its own for the purpose of raising the pressure of the urine with the view of overcoming the resistance to its outflow. The same theorem, when applied to the uterus, explains the reason why an abnormally large collection of liquor amnii renders the organ almost powerless in expelling the fœtus, and also explains why letting a quantity of liquor amnii escape facilitates its expulsion. The author exhibited some specimens of hearts hardened under moderate interventricular pressure, and proved that if the thickness of the wall at different points be substituted for the tension (to which it may be taken as proportional), the formula

$$t \left(\frac{1}{r_1} + \frac{1}{r}\right)$$

is constant, or that the thickness of the heart at any point bore a definite relation to the curvature at that point. The want of a tendency to heal in varicose veins was also explained in a similar way, for the more dilated the vein the higher the tension in its walls, and the less availed any effort it could make at contracting to its normal size. The author also deduced that in an adult heart the pressure in the left ventricle is about six times and a half that of the right. There is reason to believe that the pressure in the left ventricle is a little over nine feet of water; that in the right would, on this assumption, be equal to a head of seventeen inches of water.—Professor FRASER doubted the applicability of such precise mathematical rules to structure in animal bodies. He would like to know if Dr. Woods' conclusions might be applied to all hearts.—Professor BIRMINGHAM said that in applying these conclusions to the heart of man, he would like to hear from Dr. Woods how he accounted for the distribution of the columnæ carneæ on the interventricular septum. In the left ventricle above, where the curvature is most open, the columnæ carneæ are almost absent, while they are numerous below, where the curve is reduced. On the right side of the septum, which is convex, the columns are much better developed. Professor Birmingham also referred to an old theory of the use of the columnæ carneæ—namely, that by whipping the blood they caused it to give off its gas more readily, as when flat soda-water is whipped up it gives a renewed discharge of gas. He much preferred Dr. Woods' scientific explanation.

THE LAHORE MEDICAL SCHOOL.—The Punjab Government has provisionally sanctioned an additional professor to the Lahore Medical School, pending reference to the Secretary of State for India.

THE WREXHAM INFIRMARY.—The annual report for 1891 (the fifty-ninth) shows that the good work of the charity is year by year being extended. The cots in the children's ward have all been nearly constantly occupied during the year. The continued generous support of the working classes in the district had appreciably relieved the committee from anxiety in the financial position of the charity. The sum of £400 had been invested in the course of the year, and the invested funds now amount to £2150. A nursing institute has been established in connexion with the infirmary, and the work, for nearly three months of its existence, had been successful and satisfactory.

Reviews and Notices of Books.

A Practical Treatise on the Diseases of the Ear. By D. B. ST. JOHN ROOSA, M.D., LL.D. Seventh Revised Edition. New York: William Wood and Co. 1891.

THE fact that this well-known work has reached its seventh edition is a sufficient proof of its excellence and general appreciation. The present edition is in some respects an improvement upon the others, for the author has been sensible enough to omit certain speculative and theoretical paragraphs upon the value of electricity as a diagnostic agent, which he now frankly confesses have not sufficient basis to be of practical utility.

The book opens with a learned, laborious, and interesting historical account of otology. Throughout the treatise the historical accounts of methods of treatment are well sustained, particularly those upon perforation of the mastoid process. The author truly remarks that there is no department of medicine in which so much has been written with so little exact knowledge. He certainly does not err in this respect. The book is valuable, inasmuch as the author has been at considerable pains to separate the wheat from the chaff. His conclusions are fearlessly stated, and gathered not so much from the writings of others as his own large experience. Any surgeon carefully reading this work will be materially aided in discriminating between curable and hopeless diseases. Aural surgery largely suffers from treatment directed to incurable cases. This the author of this book does not hesitate to point out; indeed, he plainly states that chronic proliferous catarrh is an incurable affection. He also gives us a plain opinion on the value of operations upon the tympanic membrane and ossicles in non-suppurative affections of the middle ear, and plainly hints at their experimental nature and generally disappointing results. Dr. Roosa speaks in condemnation of operations upon the nose in cases of deafness, and he shares in the opinion of some others that those who now enthusiastically adopt and advise these operations will in time relinquish them. Another excellent feature of this book is the abundance of well-selected illustrative cases, which greatly enhance the clearness and clinical value of the descriptions of varieties of disease. The work is thus far from being an elementary one; yet it may well be studied even by a beginner. Aiming as it does at being a very complete treatise, it is to be regretted that here and there omissions occur upon which an author of this note should be expected to give us in detail the value of his undoubted great experience. The important and complicated subject of "malingering" deafness is very shortly dismissed, and "hysterical" affections, often most difficult to detect and deal with in practice, do not receive the notice they deserve. In the description of the affections of the external ear there is no notice of lupus erythematosus or of Raynaud's disease. Again, in the article dealing with the cerebral complications of suppurative middle-ear disease, we think the symptoms of cerebral abscess should have been more fully discussed, with the operations for its relief. In connexion with this it may also be urged that the author hardly sufficiently recognises the extent and value of the work that has been done on this subject on our side of the Atlantic.

The chapter on Deaf-mutism is a good one, and the extensive tables given of this affection are most interesting and important. We think, in regard to this part of the subject, that more attention might have been devoted to the description of the methods to be employed for estimating the amount of hearing in children.

The book is illustrated by 140 woodcuts. These are generally well executed. Taking a general estimate of this book, it may safely be pronounced to be one of the best treatises on the known diseases of the ear in the English language. As such it will be of great value to the student and the practitioner.

The Principles of Chemistry. By D. MENDELÉEFF. Translated from the Russian (Fifth Edition) by GEORGE KAMENSKY, A.R.S.M., of the Imperial Mint of St. Petersburg. Edited by A. J. GREENAWAY, F.I.C., Sub-editor of the Journal of the Chemical Society. In Two Volumes. London: Longmans, Green, and Co. 1891.

CHEMICAL science probably received no greater impetus than when the law of the periodicity of the elements was firmly established about the year 1870. Chemists do not hesitate to ascribe to the Russian chemist, Mendeléeff, whose painstaking and accurate observations have since excited universal admiration, the credit of elaborating and developing this law to such a pitch of perfection as to enable him, with his clear and characteristic foresight, to foretell not only the existence, but also the properties of unknown elements. But the germ or essence of the law was beyond cavil contained in a paper on the Law of Octaves communicated to the Chemical Society in 1866 by our own countryman and colleague, J. A. R. Newlands. With this communication Mendeléeff confesses he was not acquainted, although in the work under notice he rather frankly refers to Roscoe, De Boisbaudran, Nillson, Winkler, Brauner, Carnelly, Thorpe, and others as the true founders of the law (the further development of which, he says, still awaits fresh workers), inasmuch as they verified the adaptability of the periodic law to chemical reality. Putting quibbling on one side, we may accept that the conception of the law of octaves or the periodic functions of the elements is due to Newlands, and later also to Mendeléeff; but to the latter chemist we owe the development of the law, so that it now shares an importance equal to that of the law of gravitation itself. In short, Newlands might be called the discoverer and Mendeléeff the master of the periodic law.

Messrs. Kamensky, of the Imperial Mint, St. Petersburg, and A. J. Greenaway have done well to translate the eminent *savant's* work, and English students may now read the story of the principles of chemistry just as they are set forth and charmingly taught by the illustrious Russian philosopher. The work possesses more than ordinary interest; it marks an important epoch in the history of chemical science, for it was in preparing for the first edition of this book that the author was led to those considerations which resulted in the discovery of the periodic law in its present form. In regard to the treatment of the subject, it would amount to presumption to suppose that there would be anything likely to meet with our disapproval. Suffice it to say that the way he has dealt with the subject betrays the true spirit of the philosopher. He expresses the belief, for example, that the time has come to turn aside from visionary contemplation, from platonic aspirations, and from classical verbosity, and to enter the regions of actual labour for the common weal, and to prove that the study of science is not only an excellent education for youth, but that it instils the virtues of labour and truth, and creates solid national wealth, material and mental, which without it would be unattainable. Science, which deals with the infinite, is itself without bounds. It is gratifying to find that one so eminent as Mendeléeff joins issue with those, and ourselves amongst the number, who boldly denounce the pernicious system of teaching on strictly examination lines and for the mere purposes of cram. A schoolboy of average intelligence would read through the chapters in large type with interest and profit, while the advanced student will find in the footnotes in small type details involving the discussion of theory, and details of a historical as well as technical character. The beginner is not suddenly

Digitized by Google

introduced to a consideration of hard and new facts concerning a substance he never heard of, but to an account of the simple and familiar substance, water and its compounds. Then follow eight chapters on the non-metallic elements and their relations. In this dissertation all mention of the halogens is omitted until in the tenth chapter sodium chloride, so familiar to everybody as common table salt, is described. Then come the chlorine group, or the halogens. Salt treated of in the chapter alluded to involves of course a reference to the metal sodium to which the attention of the reader is more fully drawn in Chapter 12, an account of spectrum analysis being opportunely included. The metals, potassium, lithium, &c., follow, in natural sequence. Taking advantage of the student's knowledge so far, he is next introduced in the closing chapter (14) of the first volume to a consideration of the valency and specific heats of the metals; magnesium, calcium, and barium being also dealt with in this section. The first chapter in the second volume is devoted to the subject upon which no greater authority than Mendeléeff can speak—that is, the grouping of the elements and the periodic law. This, to us at any rate, is the most interesting portion of the work, and the footnotes, which enter into historical details of interest, and more fully into theoretical considerations, are here assigned a greater space than the text. The possibility of foretelling the properties of still unknown elements, the logical way Mendeléeff predicted the properties of a new element, and the subsequent discovery of germanium by C. Winkler, the actual properties of which were found to entirely correspond with those which were thus foretold, form a fascinating story. Interesting is it also to hear that when in 1871 Mendeléeff wrote a paper on the application of the periodic law to the determination of the properties of yet undiscovered elements, he did not think he should live to see the verification of this consequence of the law; but such was to be the case. Three elements were described—ekaboron, ekaaluminium, and ekasilicon, and after the lapse of twenty years he had the indescribable pleasure of seeing them discovered and named after those three countries where the rare mineral containing them are found, and where they were discovered—Gallia, Scandinavia, and Germany. We are tempted to linger over and discuss many details of an equally absorbing interest, but space does not permit us to recount anything like all the brilliant results which followed upon this law, and we must refer our readers to the scholarly papers contained in the appendix. The first is a lecture delivered at the Royal Institution on May 31st, 1889, and bears the title of "An Attempt to Apply to Chemistry one of the Principles of Newton's Natural Philosophy." The second is the substance of the Faraday lecture delivered before the Fellows of the Chemical Society at the Royal Institution on June 4th, 1889. It is entitled "The Periodic Law of the Chemical Elements." As illustrating the marvellous exactness with which he was able to foretell new elements consequent on a knowledge of the law, we cannot resist quoting a few lines from this memoir. "I foresee," he said, "some more new elements, but not with the same certitude as before. I shall give one example, and yet I do not see it quite distinctly. In the series which contains mercury, lead, and bismuth we can guess the existence of an element analogous to tellurium which we can describe as di-tellurium, Dt having an atomic weight of 212, and the property of forming the oxide $Dt O_3$. If this element really exists it ought in the free state to be an easily fusible, crystalline, non-volatile metal of a grey colour, having a density of about 9·3, capable of giving a dioxide, $Dt O_2$ equally endowed with feeble acid and basic properties. The compounds of the new metal will be easily reduced, and it will form characteristic definite alloys with other metals."

Following on the discussion of the grouping of the elements and the periodic law the nine remaining chapters deal with the rest of the elements classified according to its requirements. No pains have been spared to bring the subject matter into harmony with the results of modern research, and a description of the industrial processes of recent introduction has not been overlooked. In exemplification of this, we find the research of Moissan on fluorine referred to on page 483, and a description of Chance's process for the recovery of sulphur from alkali waste on page 197.

English-speaking students of chemical science owe a real debt of gratitude to the translators of this volume, inasmuch as in giving as far as possible a literal rendering of the original work, so that the spirit of the master, as it were, may be caught, they have afforded them the opportunity of reading and studying one of the most entertaining and instructive accounts of the progress of chemical science with which we are acquainted, and to review which has afforded us much pleasure and reward.

On Harelip and Cleft Palate. By WILLIAM ROSE, M.B., B.S. Lond., F.R.C.S., Professor of Surgery in King's College, London, and Surgeon to King's College Hospital, &c. London: H. K. Lewis. 1891.

MR. WILLIAM ROSE enjoyed special advantages in his early professional life as an assistant of the late Sir William Fergusson, and it is not to be wondered at that he should have devoted special attention to a branch of surgery in which his master so greatly excelled. Having had considerable experience in the operative treatment of harelip and cleft palate, he has done well to lay the fruits of it before the profession; and no exception whatever is to be taken to the form in which it is done. The book is thoroughly practical, candid, and unbiased, and does equal credit to the author's professional skill and literary ability. Mr. Rose's colleague, Mr. Carless, has contributed the chapter on the development of the upper jaw, palate, nose, and lip, which affords an admirable account of this interesting section of human embryology.

Manual for the Physiological Laboratory. By V. D. HARRIS, M.D. Lond., and D'ARCY POWER, M.B. Oxon. London: Baillière, Tindall, and Cox.

PRACTICAL work in all the branches of medicine has during the last few years received much attention in training schools, and a large share of the examination for the diplomas and the various qualifying bodies consists not so much in eliciting what the candidate can say, but more and more the crucial test is coming to be what he can do. In the domain of physiology, which forms the basis of all rational medicine, the value of practical knowledge and practical methods can scarcely be over-estimated, and this volume is so constructed that its use in the laboratory cannot fail to greatly aid the student in acquiring both. Familiarity with the microscope is essential. In this volume it is described and illustrated in a full and efficient manner. Histological methods, including a description of the various microtomes, methods of staining, mounting, and injecting specimens, are given in detail. The second part of the book is devoted to practical methods of viewing and preparing for consideration and judgment the various tissues of the body, and the last portion—Practical Physiology, strictly so-called—has been adapted to meet the requirements of senior students preparing for the higher examinations in physiology. Coming from the hands of such practical physiologists as are the authors, the volume before us cannot but put the reader into possession of the most modern style of inquiry into physical functions, and the student cannot fail to derive great assistance in his laboratory work from an attentive perusal of its pages.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 20, 1892.

FEW people doubt that the water-supply of London will before long be taken over by the London County Council. Extravagant fears, and hopes perhaps equally extravagant, are felt in regard to the proposed change. As to the fears they are certainly chimerical. In England we do not annex other people's property without compensation, and it is certain that if the London companies part with their valuable rights they will do so on equitable terms. Probably they will receive more than the actual market value of their shares. No scheme that can be adopted by an English Parliament will injure the value of the property which to so many people is a matter almost of life or death. On the other hand, the advantages to be gained by the public in such a conversion, although upon the whole very evident, are not without some elements of risk. For the assumption of all water rights by London would involve very considerable expenditure, and if a London County Council pledged to penurious economy were elected, the work might be insufficiently done, while the benefit of the great experience gained by the present private companies might be lost. Upon the whole, it appears highly probable that London would gain, as the great towns of the North have gained, by a municipal management of the water-supply.

We are anxious to do full justice to the London water companies. They were not to blame for the bad supply which, even in quite recent times, led to or fostered epidemics of cholera. Of late years they have done their best to improve the supply. Doubtless their action was stimulated partly by the action of Parliament, and still more by the growing force of public opinion and public knowledge. Companies which pay dividends cannot be expected to be anxious to incur unnecessary expense; but the London water companies are entitled to full credit, not only for an earnest endeavour to meet the demands exacted by the progress of sanitary science, but also for skill and energy in meeting them. London water is a very different thing from what it was when, in the not far past, it was our duty to denounce it, not only as an incessant danger to public health, but also as a convicted and notorious offender against it. Some of the older among our readers may remember the time when we had to record not only constant turbidity in the water-supply, but also the frequent presence of living organisms of all kinds. The stoppage of a water-pipe by an eel which had grown and fattened in it was not an infrequent thing. The compulsory removal of the intake from the Thames to places above Hampton effected a great improvement, while the more careful supervision of the river, and, above all, more efficient filtration, were hardly inferior in their beneficial effects. We admit that formerly we, together with most sanitary authorities, underrated, as many are now inclined to trust unduly to, the value of filtration. It is now fully recognised that careful filtration, even sand filtration, diminishes in a most important degree the danger of zymotic contamination. Filtration is now carried out with great care, and the water supplied to London seldom shows any urbidity perceptible to the eye. Even now further improvement might probably be effected, and it is a matter of wonder to us that powdered gas coke, the value of which as a filtering agent has been so conclusively proved by Professor PERCY FRANKLAND, has not been employed. Possibly it has been tried on a sufficiently large scale, and has been found unsuitable; but if so, no record of such experiments has reached us. On the other hand, it must not be forgotten that in the classic researches of Professor BURDON SANDERSON and Dr. E. FRANKLAND on the cholera virus it was shown that the rice-water discharges of cholera, enormously diluted with water and carefully filtered through Swedish paper, were still capable of communicating the disease to mice, and that there are many other examples on record of the futility of even apparently perfect filtration.

It is well known that the water-supply of London is at the present time derived from the following sources: the Thames above Hampton, the New River, the Lea, and deep wells. Of these the Thames is the most important, and for our present purpose the others may be ignored. Now while recognising to the utmost the value of modern improvements, we find ourselves unable to abandon our old belief that the Thames affords a most unsatisfactory water-supply. The Thames drains a large and highly populous area, and pollutions of all kinds pass inevitably into it. Every storm of rain carries down in muddy streams the washings of towns, villages, manured fields, and pigstyes. In spite of all care human sewage certainly finds its way into the stream even at distances not far above the intakes of the great companies. At the mouth of the Wey, close to Shepperton, a cluster of houses with cesspools certainly pollute the water, for the cesspools fill during flood time and empty as the water recedes. Such at least was the state of things at the time of our last inspection, and we have no reason to suppose that any change has been effected. This, at all times unpleasant, might evidently become a source of urgent danger if a single case of cholera or choleraic diarrhœa occurred in one of the cottages. In the same way barges and even house-boats, in spite of the prohibitions of the Thames Conservancy, might evidently and at any time communicate some deadly pollution to the water-supply. London would then be protected only by the filters, and surely nobody would drink with comfort water which, having received the cholera virus, had been purified solely by passage through sand. As to other pollutions we have ourselves seen the putrid bodies of dead dogs floating in the river within half a mile above the intakes of the companies.

One other argument in regard to the present London water-supply must be noticed, although it has lately been stated by Sir T. FARRER with very great force. The present water-supply of London will before many years have passed be insufficient. After seasons of drought the water companies draw off from the Thames and the Lea almost if not quite as much as could possibly be permitted. Any considerable extension of the intake would either be impossible or would leave the river an empty and muddy ditch. If, therefore, the water-supply of London remains in the hands

Digitized by Google

of the present companies they will have ere long to face the necessity for some great extension of their supply. It is evident that if the extension of London continues at its present rate the existing supply will be found inadequate ere long in regard to quantity as well as quality.

Twenty-five years ago or thereabouts a number of proposals for a new supply of water to London were discussed; and on a future occasion we may find it desirable to review these schemes, some of which have become impossible, while others are still worthy of attention. The subject has suddenly acquired a new interest, as the Government has promised yet another Royal Commission of inquiry. Although our faith in Royal Commissions has been rudely shaken of late years, not from their inefficiency, but from the systematic way in which their conclusions have been ignored, it must be admitted that before action is taken in a matter of such magnitude the latest results of scientific investigation should be considered.

IN the January number of *The Climatologist* (Philadelphia) there appears a paper by one of the editors, Dr. J. M. KEATING of Colorado, on "The Rest Cure in Phthisis." The main contention of the writer is that in physical rest under good hygienic conditions, and combined with superalimentation and tonic measures generally, we have one of the best means of re-establishing and maintaining nutrition in phthisical patients. The treatment of phthisis has in the main followed one of two directions—the effort to find some agent capable of arresting the infective and destructive processes in operation, and the adoption of measures of which the great aim is the promotion of nutrition. The former of these, however well conceived *a priori*, has, as we know from bitter experience, been a failure in practice; whereas the latter, although obviously more or less of a *pis aller*, has always achieved a considerable and encouraging amount of success. We endeavour to promote nutrition by careful feeding, tonics, a well-ordered life, change of air, climate, &c. Dr. KEATING'S paper raises the very apt and important question whether, in addition to these measures, regarding the utility of which we are all agreed, we should advise rest or activity. The prevalent idea amongst practical men is, we take it, that if a case of phthisis be far advanced and much debility and emaciation be present, rest is indicated not as holding out any hope of cure, but simply because effort is difficult and painful to the patient and achieves no good purpose; whereas in early cases of phthisis, with nutrition still fairly well maintained and a considerable amount of physical vigour still remaining, exercise is believed to be desirable as tending to promote appetite, digestion, and nutrition, and to help the expansion of the affected lung. Exercise, further, involves usually life in the fresh air, and removal more or less from the vitiated atmosphere and the habits of invalidism of the sick-room. Hence, in the opinion of most authorities, are most probably explained the good effects which so often follow a resort to high altitudes, and the adoption of the hardy and vigorous modes of life for which the mountain sanatoria offer at least considerable inducements.

While the above ideas are more or less the accepted dicta and the working rules of most physicians who have given great attention to the study of phthisis, yet we are all alive to the fact that much injury is sometimes done by the unguarded recommendation of active habits in unsuitable cases, and the reminder that in certain instances rest rather than activity is indicated is not inopportune. We should be glad of any evidence that would help us to differentiate the two classes of case, as the distinction is without doubt a real and practical one. It would be a very great misfortune if from one extreme we were to pass to the other, and accept the doctrine that rest, inactivity, and invalidism were the points to be aimed at in phthisis—a doctrine that had a long trial, and of which the results were most disastrous. Dr. KEATING quotes Dr. WEIR MITCHELL, who speaks as follows regarding the application to phthisis of his well-known methods of super-alimentation, massage, and electricity, which have achieved such good results in cases of nervous breakdown:—"I have ventured, without much hope, to treat three cases of phthisis in the same manner. There are cases of this nature in which exercise wearies; there are others which we cannot, for various reasons, send away to more genial climates; and in such instances we are driven to stand by, and, with no more hope than oil and tonics give, merely watch the slow decline of our patients. I believe that sometimes, and especially in the very earliest stages of consumption, my treatment will save a small percentage of such people; but as yet I only venture to make the suggestion, and wish distinctly to state that my experience in this form of its usefulness is limited." These are cautious words, and do not offer any very substantial basis of opinion. Dr. KEATING goes somewhat further, and mentions several cases in which "massage, electricity, Swedish movements, respiratory gymnastics, cold surface sponging, milk diet, and sensible rest" seem to have achieved a cure. He teaches that "for the unfortunate many who are obliged to antagonise soil and climate influences, who are obliged to withstand dampness, want of sunshine, and great changes, a 'rest-cure' treatment should have added to it the systematic inhalation of compressed oxygenated air, possibly medicated, and also a thorough course of pulmonary gymnastics," and to these measures in combination he looks with considerable confidence.

It is notable that Dr. KEATING, while strongly advocating physical rest, no less emphatically urges the importance of those measures which tend to exercise the lungs. We all recognise that one of the chief, perhaps the very chief, reason for advising active habits is that such habits bring the lungs into fuller play, promote the circulation of pure air in the pulmonary alveoli, and tend to expand the contracted and cicatrised lung. It is a fair question how far these ends might be achieved by pulmonary gymnastics as distinct from general physical exercise. We suspect much difficulty will be met in carrying out pulmonary gymnastics with the requisite regularity and thoroughness. We have also to remember that regular physical exercise involves the very important points of fresh air and mental distraction, and that these cannot be ignored with impunity.

Dr. HERMANN WEBER some years ago advocated a plan which he had found useful in cases of active and pyrexial phthisis. This was the erection of hammocks in sheltered

Digitized by Google

and sunny positions, the patient to spend as nearly as possible the entire day in them, fresh air being thus secured in combination with rest. The obvious difficulty in the way of this suggestion is the question of climate, such a measure being clearly impracticable unless warmth and sunshine can be reasonably expected.

It is probable that the "rest-cure in phthisis," if ever extensively employed, will be found to involve special difficulties of its own. We have the awkward fact to face that most phthisical patients at some stage of their malady become dyspeptic, and that super-alimentation and rest will probably be found impracticable in such cases. Then, experience seems to prove that our most valuable drug or food in phthisis—viz., cod-liver oil—is rarely well tolerated unless the patient be able to indulge in regular physical exercise. Still, we need a reminder sometimes that the off-hand recommendation so often made to patients suffering from phthisis of "plenty of exercise and fresh air" is a very dangerous and unscientific piece of advice and that we need carefully to distinguish between those cases in which exercise and activity seem to offer the best hope and those in which rest fulfils, at all events, a very useful function.

ALTHOUGH the report from the Committee of Delegates of the two Royal Colleges on the scheme for a five years' curriculum was received and adopted by the two Colleges in the second week of January, we understand that the synopses indicating the ranges of subjects in the various examinations will not be issued until some time in March. Meanwhile it may not be inopportune to consider the position assigned to one of the subjects which has given, and, indeed, seems still to be giving, the greatest trouble—viz., materia medica. The chief cause of difficulty appears to be the desire to treat this subject as one which might, and perhaps should, be in part studied before registration, and before the commencement of the ordinary studies at a medical school. This notion, although it probably had its origin in the old days of pupilage, still appears to present certain attractions to those who think that a great deal of useful knowledge may be picked up in the desultory instruction likely to be given by a member of the Pharmaceutical Society, or in the ordinary routine of a public hospital, infirmary, or dispensary, or of general practice. During many years this attempt to crowd in some kind of information before registration has been upon its trial at the examinations of the Conjoint Board, and the results, so far as medical education is concerned, have been disastrous. Students have been encouraged to present themselves for examination in the medicinal actions of drugs before they could possibly be familiar with the terminology of physiology or therapeutics, and the outcome has been most discouraging to all concerned. The percentage of rejections in this subject has been wholly disproportionate to its importance, and although the examiners in materia medica have thus practically indicated that an impossibility was being attempted, and indeed have, we believe, made representations to that effect, no change was sanctioned until a protest came from the examiners in medicine against the ignorance of students presenting themselves at the final examination. It has been asserted that many aspirants for qualification have been found lamentably at fault when asked to prescribe for the simplest maladies, and that poisonous drugs have been ordered in doses which betrayed complete ignorance of toxic properties. The complaint having reached a climax when students and examiners were equally dissatisfied, it has at last been resolved to attempt something by way of improvement. In the new scheme it is set forth that before the third examination students shall have attended a course of lectures on pharmacology and therapeutics during not less than three months, and for the purposes of examination the subject of materia medica has been subdivided into practical pharmacy, pharmacology, and therapeutics. The first division, practical pharmacy, may be taken at the candidate's option (or peril) at the first or the third examination, and as this branch may be studied almost anywhere it scarcely seems worth very much consideration until the issue of the synopsis of examination. With regard to pharmacology and therapeutics, however, the case is different. In the published regulations they appear under the heading of medicine, and they are associated under that heading with medical anatomy, pathology, forensic medicine, and public health. According to these regulations pharmacology appears to be defined as being equivalent to the "physiological action of drugs." This definition is, doubtless, somewhat new and somewhat arbitrary, but there can be little real objection to it if this subject is not divorced from that of therapeutics. Taken together, the terms may be regarded as embracing a knowledge of the actions of drugs both upon the healthy body and in disease, and thus there could be no chance of misunderstanding as to their scope. It is rumoured, however, that it is possible, or even probable, that pharmacology and therapeutics will be separated, the latter subject being reserved for the examiners in medicine. The advantage of such separation is not obvious, since if they desire to satisfy themselves about the student's knowledge of prescribing, of doses, or of the appropriate remedies to be employed in any given case, it was always, and would continue to be, within the power of the examiners in medicine to test this knowledge either in the paper, or, better still, during the practical examination. On the other hand, the separation of therapeutics from pharmacology would probably lead to confusion and discussion. If pharmacology means physiological action only, examiners in this subject would be precluded from touching upon many of the most important actions of some of the chief drugs, and the association of ideas between the physiological and the therapeutic action would be lost. It has often been asserted that the basis of rational therapeutics lies in the application of physiological knowledge, but it has never been considered that pharmacology or the physiological action of drugs was capable of standing alone. If this subject is to be treated in a separate paper, it is probable that it will soon attain very undesirable prominence; while therapeutics, if taken as a small part of a composite subject, will be proportionately belittled. Both for purposes of study and for purposes of examination pharmacology and therapeutics should be linked together. This has been recognised so far as the regulations affecting the teaching by lectures are concerned; it will be much to be regretted if the rumours

Digitized by Google

of separation of these subjects eventually prove to be well founded, and thus the proper balance is upset in the final arrangement of what should be mere matters of detail.

Annotations.

"Ne quid nimis."

THE GRESHAM UNIVERSITY.

THE Committee of the Privy Council has consented to the change of name of the proposed Teaching University, and the Draft Charter, with this alteration only, has been laid on the table of both Houses of Parliament. There will evidently be a considerable opposition to its passing through the House of Commons, as objections have been raised to several clauses by different bodies; but it is impossible for any changes to be made therein, as it must be passed or rejected *en bloc*. Most of the objections on the Arts side are urged against the collegiate training, which is the key-stone of the Charter, the objectors being in favour of recognising evening class instruction in its stead. The difficulty of securing adequate certificates of any proper course of study under such circumstances led to the abandoning of certificates altogether in Arts and Science in the University of London, and the same difficulty would probably arise in the case of the new University. Thus a second purely examining body in London would be created, and this with the disadvantage of being a merely local one. It is stated that out of the large number of persons attending the classes of the University Extension Society in London during the year 1890 only one completed the course, so that there is very little evidence of a continuous curriculum of study being followed by such students. The arguments for the Charter from the Arts' standpoint have been well put by the Bishop of London in a letter to the Lord Mayor expressing his gratitude to him and to the Gresham Grand Committee for uniting the London Teaching Colleges, King's and University, with the old Gresham foundation. Unfortunately, the Bishop of London, Sir John Lubbock, Lord Ripon, and others have altogether ignored the medical side of the scheme, and the question has thus been treated as if it were only one of amalgamating King's and University Colleges with Gresham College. We would point out that as the Royal Colleges of Physicians and Surgeons and the University of London have failed in passing their schemes, the success of the present movement alone offers a prospect of removing the disabilities under which London medical students are now placed. The objection of Victoria University to the proportion of the medical element being so large in the Council as fourteen, possibly sixteen, in forty, is very unfair to the medical teachers in London, who are probably quite 300 in number, and whose influence will doubtless be very great, but certainly not "paramount." The contention that such a Council will exert its influence to unduly lower the scientific training of the graduate is an unjust reflection on the London medical teachers, who will surely be as jealous of the reputation of the degrees conferred by them as are the teachers elsewhere. No safeguards against lowering the standard of degrees are inserted in the Charter of the Victoria University itself. If the Gresham degrees were unduly lowered, they would soon become worthless as marks of professional knowledge. A statement of the reasons why the medical schools of London should form a large part of the proposed Gresham University has been drawn up by the delegates of the various medical schools, and will shortly be made public, so that we hope that more attention will be given to the importance of the medical aspect of the question.

THE FOOT-AND-MOUTH DISEASE.

THE Government officials have evidently not succeeded in repelling the invasion of foot-and-mouth disease alluded to last week, for up to the present date there have been outbreaks in different parts of London and Kent, one of them as far distant as the Isle of Sheppey. There is much reason to fear a further extension, as the origin of some of these outbreaks is difficult to trace. It would almost appear as if the malady had obtained a foothold in London before the arrival of the incriminated Danish cattle, for the Government of Denmark has intimated that it is not present in that country; therefore the infection could not come from that quarter of Europe. Already the invasion has caused much inconvenience, hardship, and loss, and in view of the fact that there are now only four small countries from which live cattle can be safely obtained—Sweden, Norway, Spain, and Portugal—the question may well be asked why the importation of living beasts should be tolerated at all. The animals are generally subjected to much suffering in transit, and, considering that contagious disorders are so rife among them on the Continent, great risk is always incurred of having infection brought here with these importations, as in the present instance. It would be far better to depend upon dead meat from abroad than live stock importations. Should the malady become prevalent, then it must be remembered that the milk is infective, and prudence demands that, in localities where there is any chance of that fluid being derived from diseased cows, it ought to be boiled, especially if intended for young children.

FOG.

FOG has long been a subject ripe for legislation, and the reply given by the Marquis of Salisbury to Viscount Middleton in the House of Lords last week was, it must be admitted, somewhat disappointing. It contained no very distinct promise of any attempt being made out of the resources of science to grapple early with the difficulty. He agreed, however, that there were certain remedies which might be adopted if it were expedient to carry out a particularly drastic line of legislation. Considering that at the present time there are no fewer than 700,000 houses within the metropolitan area, in which no less than 40,000 tons of coal are being daily consumed, the remedy, if it is to be a remedy at all, must of necessity be a drastic one. This admitted, what form or shape is it to take? Coal for the present is, and probably will be for a long time to come, our chief source of fuel, and it is with this kind of fuel that we have to deal. The adoption of one particular kind of fuel — viz., anthracite, which is to all intents and purposes smokeless — has been suggested. But can this be carried out in practice, seeing that the yield of ordinary household and steam coal in our collieries far exceeds that of anthracite, while, as Lord Salisbury suggested, the price of that class of coal would be so enormously increased as to prevent its use for all ordinary purposes? It has been boldly proposed also to burn the coal in closed chambers, as in the retorts of our gas works, at a fixed point in or near the city, and so to supply the metropolis with gaseous, and hence smokeless, fuel. If any step may be characterised as drastic, surely this is one. Then there is the question of the enforced adoption of certain stoves and fireplaces, which by their construction shall ensure perfect combustion and the production of invisible or smokeless gaseous products. So long as coal is our common fuel, the remedy, it seems to us, must lie in the

Digitized by Google

general adoption of some such arrangement. We have always shown a lively and practical interest in this vitally important matter, because it is one which affects the health and well-being of a large proportion of the community. At the present moment we are engaged on a prolonged and exhaustive inquiry into the action of a new stove which is said to produce no smoke, although it is stated to burn the commonest kind of coal at an economical rate. We hope to lay before our readers the results of this inquiry in the course of a few weeks. In no case can it be supposed that scientific measures will prevent the inevitable formation of mist; but if London fog can be stripped of its colour which is coincident with its irritating character, and which is due to the presence of carbon particles, tarry matter and sulphur, then a vast improvement will have been accomplished, and a giant stride onward in hygienic science achieved. As we have pointed out more than once, even when coal is perfectly burnt or consumed, we still have to deal with the products of combustion of sulphur, which element occurs to the extent of from 1 to 2 per cent. in most kinds of coal. Carbon, hydrogen, sulphur, and nitrogen in coal, when completely burnt in air, produce carbonic acid (CO_2), watery vapour (H_2O), sulphurous and sulphuric acids (SO_2 and SO_3), and a trifling quantity of free nitrogen. Given, therefore, the complete consumption of the coal—that is to say, that no smoke or unburnt carbon is produced,—what is to be done with the combustion products of sulphur? and how will these products (SO_2 and SO_3) alter the character of the fog? We suggested in a leading article some time ago that probably lime or any of the alkalies placed at some point in the chimney could be used to absorb these acids, and those who claim to have secured the perfect combustion of coal by the adoption of a particularly constructed stove should be induced to put this simple suggestion into practice.

THE LEPROSY INVESTIGATION COMMITTEE.

THE fourth number of the Journal of the Leprosy Investigation Committee (Macmillan and Co.), which is issued under the auspices of the National Leprosy Fund, contains an account of the proceedings of the Committee up to the close of last year. It announces the approaching publication in India of the report of the Commission sent to that country in 1890, which will include an appendix containing the results of the laboratory work. Amongst the contributions to this number of the Journal are reports on leprosy in Russia from Dr. Hellat, who records the steps taken to control the disease in the Baltic provinces, and expresses himself strongly in support of its infectiousness, and the necessity for isolation as the sole means to check its spread. Dr. Fagerlund gives an account of leprosy in Finland; and there are two communications from Brazil—one from Consul-General Abbott, and the other from Dr. Azevedo Lima—describing the Leper Hospital at Rio and the condition of leprosy in the country. Dr. Lima says that leprosy has apparently increased in Brazil of late years, but there are no precise data on the point. At any rate, he thinks there must be more than 300 lepers scattered through Rio, many of whom come from the interior. Then follows an abstract of a paper by Dr. Julius Goldschmidt, giving a sketch of the disease in Madeira, where the hospital records show a notable diminution in its extent, there having been during the last fifteen years only one or two cases admitted annually. He estimates the total number of lepers at present in the island to be seventy, or six to 10,000 inhabitants. Although phthisis is not infrequently the cause of death in leprosy, yet a phthisical patient has never contracted the latter disease. Dr. Goldschmidt says that complete isolation of all lepers and their families is the only measure which can eradicate leprosy, and he urges also the inculcation on the healthy part of the population of sound principles of diet and hygiene to enable them the better to resist it. An important contribution to the question of vaccination in relation to leprosy is made by Drs. Beaven Rake and G. A. Buckmaster, founded on observations on vaccine lymph taken from lepers at the Almora Asylum. Forty cases were examined, and in not one were indubitable leprosy bacilli found in the lymph, although in two cases there were some "suspicious-looking rods." In one of these the vesicles were raised over tuberculated ears, and in the other over anæsthetic patches—localities which, they remark, are not likely to be selected for vaccination or for obtaining lymph to be used on healthy individuals. The question of the communicability of leprosy by vaccination is fully discussed in the forthcoming report of the Leprosy Commission. Meanwhile, as evidence of the slight risk of so transmitting the disease, these writers mention the very low proportion of lepers in India that have been vaccinated, the experience gained in Trinidad, the fact that they have never seen undoubted leprosy in any child under the age of six years, and the sole known case of alleged successful inoculation of leprosy—that of Arning in Hawaii—being open to the objection that leprosy is endemic in the Sandwich Islands, and that the disease has appeared in the relatives of the inoculated subject.

INFLUENZA.

THE Registrar-General's returns for the week ending Feb. 13th bear out the opinion that influenza and its associated high mortality are fast declining in this country. The death-rate in London has further declined from 30·6 to 24·6, which is precisely the same rate as obtained at Brighton, and which, moreover, is not far exceeded by any of the thirty-three great towns in the list. The deaths in the metropolis directly attributed to influenza fell to 183, and the cases in which influenza was noted as a secondary cause to 33, the figures under these heads during the preceding week being 314 and 62. The number of deaths from diseases of the respiratory organs was 560, or only 45 above the corrected average. Dr. Tomkins, the medical officer of health at Leicester, reports that influenza is still moderately prevalent in that town, but that the type is considerably milder than last year. Dr. Cameron Kidd, the medical officer of Bromsgrove, Worcestershire, in his report for the month of January showed how much influenza had increased the mortality amongst the aged. Since his report was written he stated that there had been a marked decrease in the epidemic. We understand also that there is a similar subsidence of influenza on the Continent.

HOUSING OF THE WORKING CLASSES IN CHELSEA.

THE Vestry of Chelsea has recently received a deputation from a number of inhabitants of the parish requesting that body to move the London County Council to devote to artisans' dwellings a particular site which had been cleared a short time since for the Chelsea approach to the new Battersea Bridge. The vestry agreed to memorialise the Council in the matter, and we presume that the Council will shortly be called upon to decide the question. Considerable clearances in Chelsea, it is said, have led to the displacement of many of the working classes, and if, without undue sacrifice of public money, accommodation can be provided for working people, it is a very proper thing to do. London, however, cannot afford to be extravagant in these matters, and everything must depend upon the question whether the monetary value of the site makes it prohibitory of being used in this way. The

Digitized by Google

changes which are taking place in the metropolis displace more than poor people; small tradesmen, professional men and others, all have to give way to the necessity for metropolitan improvements. No doubt inconvenience is experienced, and every effort should be made to minimise this; but we believe that the true policy of London is not necessarily to attempt to preserve land for any particular class, but to give greater facilities for people to live outside the more crowded portions of the metropolis, and to reach their work by an increase in the train service. London is far too densely crowded in many parts, and to attempt to rehouse working people under such conditions in these localities is no act of kindness to them, nor does it show consideration for their real welfare.

INFIRMARY ACCOMMODATION FOR TOXTETH.

THE need for proper infirmary accommodation in connexion with the Toxteth Workhouse has long been pressing, and matters were in a somewhat forward condition for making the necessary provision until the guardians met again last week, when it was decided that the intended loan of £43,500 for the infirmary was to be withdrawn, and that the contractors and architects should be approached with a view of getting rid of the whole business, until at some future date the subject should be again considered. The attitude of the guardians in this respect is a very serious one. At the meeting in question it was stated that no less than 176 inmates of the workhouse ought to be in an infirmary, which means that a large number of sick people are at present inadequately provided for. And not only so, but there is no proper means for the isolation of infectious cases. Thus the admission of two cases of typhus fever rendered necessary the removal of 100 persons from the ward in which the fever cases had to be accommodated. The utter wastefulness of such a state of affairs must be obvious to all who know the value of the accommodation thus rendered useless. But this is not the only drawback. So long as infectious cases cannot be properly isolated, so long must the sick poor, who are practically detained against their wills by reason of infirmity, be exposed to a source of danger and of death to which those who are responsible for their humane and proper treatment ought not to subject them. We trust that both official and local pressure will be put upon the guardians to right the present evil.

TRACHEAL TUGGING AS A SIGN OF ANEURYSM.

THE value of "tracheal tugging" as a sign of thoracic aneurysm has been investigated by Mr. Harold Grimsdale, of St. George's Hospital, who has communicated the results of his investigation in an interesting paper in the current number of the *Practitioner*. This sign, it may be recalled, was first mentioned by Surgeon-Major Oliver in a letter to this journal in 1878 (vol. ii., p. 406), and it consists in the sense of downward traction of the larynx with the systole when the thyroid cartilage is gently raised between the finger and thumb. But little attention was paid to the sign until last year, when we published communications from Dr. McDonnell of Montreal on the subject (THE LANCET, March 7th and 21st, and April 4th), and since then the observation has been frequently confirmed in connexion with aneurysms of the arch which impinge on the left bronchus. At a recent meeting of the Clinical Society Dr. F. Taylor showed a case which presented the sign in question. Mr. Grimsdale, whilst admitting that the sign is of value, being perhaps one of the earliest indications of an aneurysm in the above situation, shows clearly that it is a phenomenon which is frequently present in the absence of any aneurysmal dilatation of the vessel. In conjunction with Dr. Ewart, an examination was made of 118 hospital patients, among whom no fewer than fifty-one presented "tracheal tugging," the males preponderating. They noticed, however, degrees in the extent to which the tugging took place, and of four cases in which it was "marked," two were cases of aneurysm of the arch, one of emphysema and bronchitis, and one of chlorosis. Seventeen cases showed "moderate" tugging, twenty "slight" (including one of probable aneurysm of the ascending aorta), and seven "very slight." It is especially noted that of ten cases of mitral disease the sign was present only in one; in four of aortic valvular disease it was present in three. It was also present in only one of five cases of phthisis. It was increased by exercise and excitement, was synchronous with the cardiac systole, and almost always more marked during inspiration than during expiration (an exception to this rule being a case of emphysema, in which it was very marked during expiration). In discussing the *modus operandi* of the phenomenon, and endeavouring to harmonise some of the apparent anomalies as regards its presence or absence, Mr. Grimsdale inclines to the belief that it depends upon the aorta being brought into contact with the left bronchus during inspiration by the downward and forward displacement of the heart. He found, further, that it decidedly preponderated in people with full chests and prominent infra-clavicular regions, whilst in the flat-chested and stooping patients it rarely occurred, even under excitement. It would seem, then, that as a positive sign of aneurysm even marked tugging may not be absolutely diagnostic; but its absence "certainly denotes absence of any gross dilatation" of the part of the vessel near the left bronchus. The best plan to obtain the sign is for the observer to stand behind the patient and to gently raise the trachea by the tips of both index fingers placed beneath the cricoid cartilage.

THE PROPHYLACTIC INFLUENCE OF TOBACCO.

DR. V. TASSINARI, of the Institute of Experimental Hygiene attached to the University of Rome, has been attempting to demonstrate the prophylactic advantages of tobacco smoking. He recalls the fact that in the eighteenth century, and even in the seventeenth, a certain number of medical men—Willis, Dimerbrock, and others—advised their friends to smoke in times of epidemic. At Strassburg, in 1842, Ruef called attention to the fact that the workers at the tobacco manufactory were exempt from almost all the prevailing epidemics. Pécholier, in the *Revue d'Hygiène* (1883, p. 523), proclaimed the same opinion, and Dr. Walter Cock of Texas was rash enough to recommend, in 1889, the use of tobacco as a preservative against phthisis. An American dentist—Dr. Miller of New York—made experiments in 1884 with the smoke of tobacco on the micro-germs of dental caries, and declared that the results were satisfactory and conclusive. Dr. Vassili of Naples employed in 1888 a small balloon, which he lined internally with a layer of gelatine containing cholera bacilli. He found that by drawing through this balloon the smoke of from one to four cigars—the number of cigars required depending on their strength in nicotine—the gelatine was completely sterilised. Dr. V. Tassinari has now repeated these various experiments, and maintains that the smoke of tobacco either entirely destroys or in any case retards, the development of the bacillus of cholera, of anthrax, and of pneumonia. Dr. Tassinari published twenty-one charts indicating the action of tobacco on various known microbes, according to the nature of the tobacco and the amount consumed. The latter varied from one to six grammes, smoked in from ten to thirty minutes. The bacilli of Asiatic cholera and that of Friedländer

Digitized by Google

(pneumonia) were always completely destroyed, no matter what sort of tobacco was used. The bacillus of anthrax resisted better, and that of typhoid was hardly affected by the smoke. As a practical result of these experiments Dr. Tassinari insists on the utility of smoking as a means of preventing the decay of teeth. He seems to imagine that women suffer more from dental caries than men, and attributes this difference to the fact that but few women smoke. It must be confessed that these experiments are not conclusive. There is a great difference between the sterilising of microbes in nutritive gelatine and in the human being. No one doubts the antiseptic qualities of nicotine. Sulphurous acid is also an antiseptic, but it still remains to be proved that London fogs and London smoke save the metropolis from zymotic disease.

METROPOLITAN PUBLIC GARDENS ASSOCIATION.

THE task which this Association has set itself is the very laudable one of securing available vacant plots of ground in the metropolis and transforming them into gardens for the health and recreation of the people. The Association is alive to the many reasons that could be urged for the existence of these open spaces in increasing numbers and dimensions. Besides the effects—mental, moral, and physical—on the individuals there is the wider consideration of sanitary effects on the population in general. The provision of public recreation grounds is not a mere question of ornamental philosophy, though of the purest sort, but it is a question of social economy and expediency. Those who live in the outskirts of the metropolis have many evidences of the growth of this already vast collection of bricks and mortar. Spots once green and fertile are now soot-begrimed and unrecognisable after the brief period of three or four years, and the consequent aggregation of the population requires yearly to be set off with more extended lung areas in this great city. This Association works in conjunction with the National Health Society. Its membership is increasing, and the good which it has already succeeded in effecting is testimony to the value of its aims. Its work is yearly increasing, and will increase so long as the builder plies his trade.

THE ETHICS OF LIFE INSURANCE AND DEATH CERTIFICATES.

A DOCTOR OF MEDICINE, who has practised for twenty years in the manufacturing districts of Lancashire, writing to *The Times*, seriously impeaches the good faith of his medical brethren in giving certificates to procure life insurance. He says that in his district it is the custom to insure the lives of pretty nearly every man, woman, and child. This is especially the case, it would seem, whenever any serious disease declares itself. And the people classify doctors as "good" or "bad," according to the talent and readiness which they show in giving a euphemism to a disease that is likely to be counted an objection by an office. There are, according to this authority, many "good" doctors who will modify phthisis of two years' duration into bronchitis of three months, cancer of two years' duration into tumour of three months, and so on. This is a serious charge, coming from a medical brother. It is true, he admits that the agents of the various offices, hotly competing with each other, are half willing to have such false and misleading certificates, and that they connive at them, seeing that they are paid according to the business they do. "Doctor of Medicine" declares that virtue and truth do not pay, and that he has had to suffer for refusing a certificate to an obvious drunkard. The evil does not stop here. One lie has to be followed by another, and the death certificate has to be incorrect. Not only so, old people and children, according to this writer, are frequently done to death for the sake of the insurance money. We cannot believe that any serious number of medical men would be parties to such fraudulent transactions, and we hope to see these injurious statements contradicted. If not, it is a matter for grave inquiry. If such charges against any medical man could be substantiated, they would surely amount to "infamous conduct in a professional respect."

SULPHONAL.

IN a lecture delivered at the Congress of German Neurologists in Baden, June, 1891, Dr. Gilbert of Baden Baden describes four cases which were treated in the Sanatorium there. Two of the patients were under treatment for the sulphonal habit, as it had become a perfect mania, so much so that the absence of it caused symptoms similar to those experienced when overcoming the morphia habit. This was not the case with the other two, but serious symptoms were evident. Besides the well-known injurious effects produced by the use of sulphonal, all the four patients were unable to write straightly and distinctly. The characters were unsteady, and in an ascending line from left to right. Attention is called to the fact that although the effects of sulphonal are well known, still it is used as freely as ever. In Germany it can even be obtained at chemists' shops without medical prescription. In conclusion, when the use of this drug seems unavoidable, it is recommended that it should be prepared as follows. Boiling water is poured on the dose of sulphonal and the mixture is cooled by constant stirring until it is just palatable. By this means precipitation is nearly avoided, and the drug enters the stomach in a dissolved form. Thus sleep is said to be generally produced in from fifteen to twenty minutes, and the troublesome feeling of weariness, enervation, &c. usually experienced by the patient on the day following the use of sulphonal does not appear.

THE PHYSICIANSHIP IN ORDINARY TO THE PRINCE OF WALES.

THE appointment of Dr. Broadbent as Physician in Ordinary to His Royal Highness the Prince of Wales will give general satisfaction to the profession. Dr. Broadbent's general reputation as a physician eminently entitles him to this post. It would be unsatisfactory if His Royal Highness had selected a mere specialist as his ordinary adviser. His health is a matter of the highest importance to the nation, and it is most desirable that it should be in the care of one who can regard it from many sides, and bring to the service a large experience.

THE INDIAN OPIUM TRAFFIC.

THE controversy respecting the Indian opium traffic still goes on much after the manner of an artillery duel at long range, and so far without any definite result. A comparison of the arguments used on either side is nevertheless instructive. On the part of the Indian Government we are met with an unqualified denial that the opium habit is decidedly on the increase in the country under its rule, even among those classes or in those localities where it admittedly prevails, and by an assertion that it is effectually held in check by legal restriction. At the same time we are told that opium smuggling tends to develop into a regular trade—a fact which at all events does not strengthen confidence in the decline of the habit. The opposite side of the question was lately presented to the public of this country in a letter by Mr. Donald Matheson, in which he criticises the position and arguments of the non-interference party. The Government of India, he reminds us, is more than a merely regulating authority. It holds a strict monopoly of the trade in opium, is at once the grower, manufacturer, and

Digitized by Google

vendor of the drug, and he is naturally disposed therefore to view the question of its use and abuse chiefly from a commercial standpoint. He points out that a statement that the opium consumption is as yet small in comparison with the population of the Indian Empire really furnishes a strong argument in favour of prohibition, inasmuch as it shows that the evil, if early dealt with in this way, may still be effectually extirpated. Finally, he quotes the authority of a declaration made by upwards of five thousand medical practitioners of the United Kingdom to the effect that the opium habit is morally and physically debasing, and that the drug itself should therefore in ndia, as in England, be classed as a poison and sold for medicinal purposes only. Nothing could be simpler or more scientifically accurate than this presentation of the subject. Thus much even the Indian Government may fairly be expected to concede, and we cannot doubt that it would do this and support the admission by practical legislation, but that there come in the rival interests connected with usage and revenue. We can all appreciate in some degree the resulting difficulty of its position, but this is no reason why the work of reform so greatly needed should be neglected. It remains to be seen whether a process of reduction, gradual if not rapid, in this injurious traffic cannot be effected without serious dislocation of present fiscal arrangements. Meanwhile we regard it as an obvious duty to maintain towards it an attitude of opposition, of which we may say that it is not the less impartial because condemnatory of the common use of a purely thera eutic and poisonous agent.

ROYAL COLLEGE OF PHYSICIANS.

THE series of lectures for the present year are announced as follows:—*Milroy:* by Dr. Francis Warner, "On the Physical and Mental Condition of School Children," March 8th, 10th, 15th, and 17th. *Goulstonian:* Dr. Sidney Martin, "On the Chemical Pathology of Diphtheria, compared with that of Anthrax, Infective Endocarditis, and Tetanus," March 22nd, 24th, and 29th. *Lumleian:* Dr. Pye-Smith, "On Certain Points in the Etiology of Disease," March 31st, April 5th, and 7th. The Milroy and Goulstonian lectures will be delivered in the theatre of the Examination Hall, Victoria Embankment.

THE LOCK HOSPITAL, LIVERPOOL.

IT is interesting at all times to contrast the position of a particular disease or operation at the present period with the views of its etiology and treatment held not exactly in the remote but in the comparatively immediate past. The reopening of the Liverpool Lock Hospital has afforded Mr. Fred. W. Lowndes an opportunity of reviewing, in the course of his address on that occasion, the history of its foundation in the form of a ward within the walls of the old infirmary, in 1749; its progress in 1833; and after a period of closure its reopening on Aug. 31st, 1891. Its important work has been performed in a quiet and unostentatious way. Increasing accommodation has been found for a class of patients with whose unfortunate maladies there is but little sympathy beyond the profession, to which, above all, they must look for assistance in times of direst trouble. By the erection of hospitals of this kind objectionable patients were removed from the general hospitals and treated by various methods, which speedily became the subject of study. Mr. Lowndes refers to what may be called the period of confusion in the treatment of venereal disorders, of misconception of its origin, and the generally erroneous nature of its dogmas. The subject is instructive from more than one point of view. The horrible scenes witnessed in metropolitan hospitals were loudly denounced so long ago as 1823 by Sir Astley Cooper, who, observing the miserable treatment of these unfortunate patients, condemned it in no measured terms: "When so infamous a practice prevails I cannot satisfy my own feelings by resorting to milk-and-water language. Patients are compelled to undergo so infamous a system of treatment that I cannot bear to witness it." These words and others like them had been repeated to the students of Guy's Hospital over and over again without any avail. On one occasion they fell on the attentive ear of one who could not rest until they were sent broadcast over the country in the columns of THE LANCET. Within a week of their publication in THE LANCET the venereal wards of Guy's Hospital were opened "under new and improved regulations." The march of progress and investigation has continued ever since. Mr. Lowndes truly remarks "that venereal diseases still demand our careful study, and it follows naturally that provision must be made for the careful observation and treatment of those suffering from them," if not in general hospitals, then in those specially set apart for such treatment. To these assistance cannot be denied on grounds either economic, charitable, humane, or moral; and, although certain pseudo-philanthropists have deemed it their duty to maintain the contrary, to the members of the profession of medicine it is not necessary to point out that a poor person suffering from venereal disease in an acute form, by whose fault soever, is as great an object of charity as any patient can be.

THE TREATMENT OF THE STATUS EPILEPTICUS.

THE *St. Petersburger Med. Wochenschrift* publishes an account of a method of treating the so-called "status epilepticus," which has been successfully adopted by Dr. Kernig. He gives the following particulars of a case treated by this method. A girl in the Obuchoff Hospital in St. Petersburg, after suffering a whole night from almost continuous epileptic convulsions, next morning was unconscious, but without any œdema of the lungs, and with a fairly good pulse. On the convulsions being renewed a hypodermic injection of 0·02 gramme of hydrochlorate of pilocarpine was given, and 1·5 grammes of camphor in an emulsion. Profuse perspiration followed, and the convulsions immediately ceased, but for an hour pulmonary œdema and collapse seemed imminent. These symptoms, however, passed off, and were followed by sound sleep and a good pulse. The patient was made to lie on her side to prevent annoyance from the excessive secretion of saliva.

THE DUSTMAN.

WILL the time ever come when our old enemy the dustman will be abolished? That his rule in many houses is still autocratic all will agree. He removes what he chooses, and will remove almost anything else "for a consideration." If "untipped" he is apt to be offensive; if "tipped," his care and attention in the removal of house refuse still depend greatly on the amount of the "tip." Of the cart in the street and the coadjutor of the dustman we have before spoken; and if we again allude to an unpleasant subject it is only to recognise that here and there a sanitary authority has done something for the public protection. The vestry of St. Giles' has made a step in advance which must have been marked with approval by many a Londoner. In this parish the open and commonly overfilled cart has been replaced by a neat iron waggon covered in segments by curved iron lids. Any one of these thrown open will receive the house tribute without serious risk of the cloud of filthy dust which commonly follows the progress of the dustman. We do not doubt that so enlightened a vestry has issued strict orders that the carts shall never be overfilled. In that case one of the smaller terrors of the London streets has been removed. The Public Health Act of 1891 gave new

Digitized by Google

powers to householders, which doubtless have had practical results; but some recent proceedings in the North London Police-court show that there is still great room for improvement. As usual, a public-spirited individual raised the question of the removal of house refuse, and issued a summons against the vestry clerk of Islington. After the issue of the summons the grievance was removed, and the summons therefore withdrawn, but not without a remark from the magistrate that the complainant had done the public good service.

CONSULTATION FEES RECOVERED BY LEGAL PROCESS.

A FELLOW of the College of Physicians is hindered by the by-laws of his College from enforcing payment of his fees in a court of law. And sometimes he has to suffer loss at the hands of ungrateful patients for want of such a power. Mr. Frederick Turner, M.R.C.S., of Buxton, brought an action against Mr. Isaac Ash, of Higher Buxton, to recover £22 fees for certain consultations with the defendant's medical adviser. THE LANCET was referred to as approving a fee of one guinea per consultation in the circumstances, the charge made with an allowance. Various practitioners of Buxton gave evidence in a similar sense. We are surprised that Dr. F. H. Collins, secretary to the Medical Ethical Association of Manchester, having been called for the defence, should, as is reported, have stated that he had never heard of a case of a doctor being consulted twenty-six times in thirteen days. He did not deny that the charges were the regular ones. The judge summed up firmly in favour of Mr. Turner's claim, and the jury, after a short absence, allowed it. The case seems to us interesting as showing that, apart from the by-laws of colleges, there is a remedy for consultants in courts as well as for general practitioners. It is well reported in the *Buxton Advertiser* of Feb. 13th.

INSANITARY DWELLINGS.

AN action has recently been heard in the Court of Queen's Bench which is of considerable importance especially because it may be expected that it will be followed by others where the circumstances are in any way similar. The Housing of the Working Classes Act, 1890, contains a provision which was previously a part of the Housing of the Working Classes Act, 1885. This provision is that "in any contract made after the passing of this Act for letting for habitation by persons of the working classes a house or part of a house, there shall be implied a condition that the house is at the commencement of the holding in all respects reasonably fit for human habitation. In this section the expression 'letting for habitation by persons of the working classes' means the letting for habitation of a house or part of a house at a rent not exceeding in England the sum named as the limit for the composition of rates by Section 3 of the Poor-rate Assessment or Collection Act, 1869." In London this is equal to a rent not exceeding £20. In the case in question the plaintiffs alleged that the tenement was insanitary, that the drainage was defective, and that the flushing apparatus of the water closet was defective so that it was without water-supply, with the result that bad smells prevailed, and four of their children eventually suffered from diphtheria and died. The defendants on their part alleged that the tenement was in a condition reasonably fit for habitation when the plaintiffs took it, and that the insanitary condition of the premises which caused the death of the children was due to the uncleanliness of the plaintiffs themselves, and to their not allowing the rooms to be sufficiently ventilated. In the end the jury returned a verdict for the plaintiffs, with £77 10*s.* damages. With the condition of the house we need not concern ourselves. It was admitted to be faulty, and it is immaterial for our purposes who was responsible for its defects. But the question may seriously be asked, Is the evidence that diphtheria is due to faulty drainage sufficiently strong for a definite opinion to be formed on this point? The published reports of the case make no reference to medical evidence on this point. It appears to have been accepted that insanitary conditions and diphtheria must necessarily be related as cause is to effect. There is not a word as to whether diphtheria was prevalent in the school which the children attended, or any reference to inquiry as to whether there were grounds for suspicion of the milk-supply. The relation of diphtheria to faulty sanitary surroundings is not of a very certain character. Dr. Thorne, discussing this subject in his recent work on diphtheria, says: "I am inclined to regard the influence of a sewage-polluted air as operating in much the same way as the scarlet fever poison, in so far as predisposition to diphtheria is concerned." But this is all, and a hasty conclusion that occurrences of this disease are actually due to such condition is not one which should be made. We need not say that we have no desire to defend persons who may let insanitary houses, nor do we fail to see that the decision in the case to which we have referred may serve as a useful stimulus to landlords. But the fact that an etiological question such as the causation of diphtheria has now attained a monetary importance makes it very necessary that it should not remain obscure. We would gladly see, if it were possible, cases of this sort referred by the Court to a sanitary expert for inquiry and report.

RULES FOR ISOLATION HOSPITALS.

THERE is a not unfrequent demand for a model code of regulations for the control and management of isolation hospitals, their staff, patients, visitors, &c., but owing to the wide differences between the institutions which have been provided by sanitary authorities no general code has ever been compiled. Every new set of rules is therefore of interest, and for the information of those who are concerned in the administration of isolation hospitals we would draw attention to a code which has just been issued by the Health Committee of the Nottingham Town Council. The rules have been compiled by Dr. P. Boobbyer, the borough medical officer of health, and have received the approval of the corporation.

PHAGOCYTOSIS IN RELATION TO IMMUNITY.

THE discussion which opened at the Pathological Society last Tuesday served to show how difficult and intricate is the question of immunity from specific diseases, and also how various may be the interpretations put upon the results of experimental observation. The physiological fact of phagocytosis is generally allowed, and there does not seem to be any serious difference of opinion as to the existence of an influence on the behaviour of leucocytes, to which the term "chemiotaxis" has been applied. But, as Professor Burdon-Sanderson pointed out in the weighty remarks that he made, the wider application of phagocytosis to protection of the organism against the attack of infective virus implies a very great addition to the known powers and properties of the leucocyte. Dr. Sims Woodhead, who naturally went over some of the ground which he has recently dwelt upon in these columns, and who, on this occasion, was the sole advocate of the doctrines of Metchnikoff, anticipated this objection in his remarks on the necessity for special stimuli to evoke the latent properties of these protoplasmic elements of the body; and although Dr. Klein, who assumed a very militant attitude towards the whole theory, pointed out the selective power of the various specific poisons for special tissues, yet it is open to conjecture that it may be just in these tissues that

Digitized by Google

the phagocytic action takes place in such diseases. Dr. Klein's criticism, founded on conditions in which leucocytes are apparently destroyed by microbes rather than the reverse, was not so weighty as were his interesting observations upon the behaviour of anthrax bacilli introduced into the lymph sac of the frog. Here he came to close quarters with the supporters of phagocytosis, since he was dealing precisely with a class of experiments upon which a large part of their argument rests. Mr. Kanthack's contribution to the debate was a thoughtful and thorough consideration of the matter. He advanced many objections to the assumption that phagocytosis by itself is adequate to explain the phenomena of artificially induced immunity. But, as we have said, the subject is one which bristles with difficulties, and it is not possible as yet to harmonise the several observations. We cannot expect that the debate will succeed in determining a problem that is engaging the profound attention of the most advanced and thoughtful school of pathologists. It will, however, serve to indicate those parts of the question which most demand investigation, and thus tend to its further elucidation.

INFLUENZA AS AN INFECTIOUS DISEASE.

UNDER the title of "Influenza and the Laws of England concerning Infectious Diseases," Dr. Sisley has reprinted a paper which was read before the Society of Medical Officers of Health. In the course of his remarks he notes with satisfaction the action which the Dover sanitary authorities considered it was "their privilege and duty" to take—viz., to issue in the name of the mayor, aldermen, and burgesses a solemn warning to the public of the dangerous and infectious character of influenza, together with the further information that the disease is often spread by careless exposure of infected persons, and ending up with the threat from the Public Health Act of the usual penalty for wilful exposure of an infected person. Counsel's opinion on the powers of sanitary authorities as to influenza is appended, but it cannot be said to advance matters very materially. Asked whether influenza comes within either the common law rule or the statutory description, it is gravely answered that "it must be within both or neither," that the question is a "very doubtful one," and that a mere announcement of intention to act on the Public Health Act would not expose the local authority to hostile proceedings, and might meanwhile do good. The advantage of making an empty threat seems very much open to question. Merely to threaten to act without the intention, and possibly the power, to do so is far more likely to lead to callous disregard of the really useful provisions of the Public Health Act than to produce any marked influence upon an epidemic which already shows cheering indications of abatement.

THE GYNÆCOLOGICAL AND OBSTETRICAL CONGRESS.

THE official programme of this Congress has just been issued. It bears the signatures of the President, Dr. Kufferath, Professor of Obstetrics at the University of Brussels, and the general secretary, Dr. Jacobs. The Congrès International Périodique de Gynécologie et d'Obstétrique will in future assemble every four years in Belgium and Switzerland alternately. Communications and discussions may be delivered or spoken in French, English, or German. Each member of the Congress must subscribe 30 fr. (24s.) or pay a composition fee of 300 fr. (£12), which will admit him to all future meetings. The opening of the first session will take place at Brussels on Wednesday, Sept. 14th, at 1 P.M., the proceedings to conclude at 6 P.M. on Monday, Sept. 19th. The sittings will be held every day after Wednesday from ten to twelve in the morning and from three to six in the afternoon. Gentlemen who wish to read papers at the Congress are requested to make known their intention before July 1st, 1892. All who desire to join in the discussion on the three chosen subjects (pelvic suppuration, extra-uterine pregnancy, placenta prævia) are recommended to send in their names to the general secretary before Aug. 15th. An exhibition of gynæcological and obstetrical instruments will be held during the sitting of the Congress. For forms of application for admission and all desired information concerning the Congress a letter must be addressed to Dr. Jacobs, General Secretary, 12, Rue des Petits Carmes, Brussels.

DIPHTHERIA AT ESHER.

IT is not many months since we sent a commissioner to report upon the prevalence of diphtheria at Esher. At that time there was a strong local feeling that the disease was in some way connected with the new system of sewers, but the evidence obtained went to show that the grounds for this belief were not very substantial and that other causes had doubtless been in operation. The disease unfortunately still prevails; and the Local Government Board have requested the Kingston rural sanitary authority to instruct Dr. Gibbes, their medical officer of health, to prepare a report as to its continuance, as to the causes of its diffusion, and as to the means taken for its prevention.

WASHING OUT THE STOMACH IN CHLOROSIS.

THE *Wiener Klinische Wochenschrift* refers to a communication by Dr. Pick, who publishes the results of some observations he made in Nothnagel's clinic to determine the relation which exists between affections of the stomach and those not infrequent cases of chlorosis in which the leading symptoms are of a gastric character. Some connexion between the two has been proved to exist in some cases of pernicious anæmia. The *Wochenschrift* does not consider that Dr. Pick's contribution gives a decided answer to the question, but points out the importance of one result of the experiments. He found, as others have done before him, in all the cases an atonic condition of the stomach, which had not digested the food taken on the previous day, although the patient was fasting at the time of the observation. In these cases Dr. Pick was able to cure the chlorosis quickly by washing out the stomach at stated intervals. In several instances no benefit had been derived previously by treatment with iron. Washing out the stomach prevents abnormal decomposition, which by auto-infection causes the blood dyscrasia. Dr. Pick, with the same object in view, and with equally favourable results, administered creasote when flushing could not be resorted to.

CEREBRAL ABSCESS.

IN the Bulletin of the Johns Hopkins Hospital the results of an examination for micro-organisms in the pus of a cerebral abscess is reported by Dr. William H. Welch. The patient, who had met with an accident ten days before his admission to the hospital, and had, the day before admission, what was called a fit, was found to have a suppurating wound below and to the outer side of the left frontal eminence. There was a depressed fracture of the skull underneath, and on this being elevated and removed the dura mater appeared normal. After the operation, for a few days the patient's general condition seemed good; but he soon became dull and lethargic, with periods during which he was much brighter. Without presenting any urgent symptoms previously, he complained of headache, and quickly passed into a condition of stupor and died somewhat suddenly. At the necropsy a large collection of

Digitized by Google

green offensive pus was found occupying the centrum ovale in the frontal region, not extending so far back as the central convolutions. The grey matter was only involved at one point, in the middle frontal convolution. Cover-glass preparations were made from the pus in the abscess, and numerous cocci were found in pairs and in small clumps. They presented the usual appearances of the staphylococcus pyogenes. An attempt was also made to obtain cultures on agar-agar, but these, tried in various ways, remained sterile. An interesting point occurs in the fact that the pus had a distinct odour of sulphuretted hydrogen, and a suggestion is thrown out by Dr. Welch that the coccus named (for no other organism was found) may produce in the brain decomposition leading to the production of this gas.

MASON SCIENCE AND QUEEN'S COLLEGES, BIRMINGHAM.

THE legal difficulties as to the amalgamation of these Colleges have been settled by Mr. Justice Chitty in the Chancery Division of the High Court of Justice. He referred the petition of Queen's College to chambers for approval of the scheme, expressing the opinion that, speaking generally, it was a highly beneficial arrangement. By the scheme the medical part of the education now carried on at Queen's College will be transferred to the Mason Science College, thus avoiding a reorganisation of Queen's College and a large extension of its buildings. We look upon this amalgamation as a precursor of a Midland University, and are pleased that such a satisfactory arrangement between colleges so distinct in their inception should have been arrived at.

HYPODERMIC INJECTION OF IODOFORM IN LOCALISED TUBERCULOSIS.

DR. WEIDEMÜLLER, in the *Münchener Med. Abhandlungen*, reports very favourably upon the treatment of localised tuberculosis by the injection of iodoform. This treatment was adopted in twenty-two cases, comprising four of disease of the elbow-joint, four of the knee, five of the ankle and tarsus, and three of the wrist. Of the six remaining cases two were due to multiple tuberculosis, two to indolent abscess, and two to fistula after resection. A solution containing from two to three grammes of iodoform in glycerine was used in each instance, with the following results: two patients were cured, eleven considerably improved, three slightly improved, and in one case only was the treatment entirely unsuccessful.

THE SANITARY STATE OF PUDSEY.

A TRENCHANT REPORT has been issued by Dr. W. L. Hunter on the sanitary state of Pudsey. There is no regular system of drainage, the becks act as main sewers, the road drains are old, shallow, permeable rubble structures, and when opened are frequently found to be more than half full of sediment, some pipe drains being "solidly full." The drains have no means of ventilation, whilst the sewage which escapes from them gets into mill-dams or directly into one of the streams which flow round the town. House drainage, too, is much the same. In some districts scarcely a house is properly drained, and, although a notice was given in 1890 that all sinks should be trapped and disconnected, hardly any of the house-owners took notice of the requirement. Much the same applies to nuisances, and it is added that, on account of what is considerately termed "leniency" on the part of the Board, very little notice is taken of any orders issued as to nuisances. The general death-rate was 21·7 per 1000 last year. This is not a specially excessive one, but the conditions obtaining in the place are precisely such as lead to sudden and heavy preventable mortalities. The building by-laws are antiquated, and damp walls and foundations, together with "jerry" structures, are not uncommon; the slaughter-houses are, in many instances, very defective; and it is clear that grave sanitary defects exist in abundance. The local press, in referring to the report, admits the energy and ability of the sanitary staff, and points to certain excellent work on their part. But it adds that Pudsey is practically in the same state to-day as it was twenty years ago.

THE TREATMENT OF ECZEMA.

THE *Gyógászat* publishes an account of Dr. Berthold Löwengard's new treatment of eczema. He had under his care a child six months old suffering from severe seborrhœa, which had resisted all the ordinary methods of treatment. Upon having recourse, however, to a 2 per cent. solution of creoline, in three weeks' time the disease had entirely disappeared, not a symptom remaining. He has made use of a solution of creoline with equally favourable results in papular and pustular eczema and in eczema of the genital organs. One of the latter cases was complicated with anal fissure, but this healed in four days after treatment with creoline and strict attention to cleanliness. Dr. Löwengard was occasionally obliged to substitute other remedies for the creoline in the course of treatment, but he succeeded in all cases in relieving the painful symptoms of the acute stage.

THE OFFICE OF INSPECTOR OF EXAMINATIONS.

THE appointment of inspectors and visitors of examinations for the General Medical Council will be made for the present year by the Executive Committee. In future the appointment will be made by the Council at its May session. For 1892 the Executive Committee will assign duties to the inspectors and visitors. The committee will meet on Monday for this and other purposes. Those who intend applying should lose no time in doing so.

THE ACTION OF STRYCHNINE ON THE STOMACH.

THE *Khirurgicheski Vestnik* publishes an account of some experiments by Gamper on the action of strychnine on the stomach. Observations were made on seven persons, five of whom were in health, one suffered from gastralgia with excessive secretion of gastric juice, and the last (Gamper himself) from gastric catarrh. The observations extended from twenty to thirty days, and during the first and last week no strychnine was given to excite the stomach. Ewald's test-breakfast was given, and observations were undertaken to determine the volume of gastric juice, the percentage of total acidity, the proportion of hydrochloric acid by weight, the digestive power of the juice, the result of fermentation and the absorbent power and movements of the stomach. Nitrate of strychnia was given at breakfast time in doses varying from 0·002 gramme to 0·005 gramme, but sometimes increased to 0·015 gramme. The activity of the stomach was increased in all respects, with the exception of that due to the ferment and the lactic acid. Gamper attributes the usefulness of the drug to the increased excitability of the medulla caused by the strychnine.

THE TREATMENT OF PULMONARY GANGRENE.

DR. O. HEWDKE of Warsaw, in the *Deutsche Medicinische Wochenschrift*, gives particulars of his treatment of pulmonary gangrene, with notes of four cases. In all these the usual remedies, such as turpentine, creasote, inhalations of carbolic acid, &c., had been tried without effect.

Digitized by Google

He then made antiseptic injections into the gangrenous tissue, and during this treatment considerable improvement was observed, amounting in one case to almost complete cure. The syringe used had a capacity of 2·5 cubic centimetres, and was provided with a needle from 5 to 7 centimetres long. Dr. Hewdke first made use of menthol, but as this caused unpleasant symptoms, he substituted a ¼ to ½ per cent. alcoholic solution of thymol, which could be well borne to the extent of from 2 to 2·5 cubic centimetres. Local irritation of the skin or subcutaneous tissue was not observed, except where the injections had been frequently repeated. The mechanical part of the treatment presented no difficulties. Immediately the needle reached the cavity a paroxysm of cough occurred, followed by free expectoration, the patient both tasting and smelling the injected fluid. Dr. Hewdke, with other observers, recommends the selection of recent cases and those presenting superficial and non-tuberculous cavities for this method of treatment.

WE regret to have to record the death of Dr. John W. Taylor, medical officer of health of the borough of Scarborough, which took place suddenly on the 15th inst. from heart disease, while visiting a patient. Dr. Taylor was J.P. for the North Riding, and was frequently engaged by the Local Government Board in investigating outbreaks of zymotic disease, and last year he made a report as to the prevalence of typhoid fever on the Teesside.

The State Board of Health of Louisville, Kentucky, are beginning the prosecution of quacks and travelling doctors for acting illegally. This is one of the many signs of a determination on the part of medical authorities in the States to advance education and to draw a just distinction between those who are and those who are not educated.

THE council of the Sanitary Institute have accepted an invitation from the town council of Portsmouth to hold their annual congress and exhibition in that town in the autumn of this year.

YELLOW FEVER appears to be raging with unmitigated fury at Santos, Brazil. As many as 150 persons are reported as dying in one day.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6459 births and 4514 deaths were registered during the week ending Feb. 13th. The annual rate of mortality in these towns, which had declined from 35·4 to 26·2 per 1000 in the preceding three weeks, further fell last week to 23·1. In London the rate was 24·6 per 1000, while it averaged 22·2 in the thirty-two provincial towns. The lowest rates in these towns last week were 16·6 in Bradford, 17·0 in Birkenhead, 17·3 in Huddersfield, and 17·9 in Leeds; the highest rates were 25·6 in Oldham, 27·1 in Newcastle-upon-Tyne, 30·6 in Preston, and 32·0 in Nottingham. The 4514 deaths included 336, which were referred to the principal zymotic diseases, against numbers declining from 604 to 440 in the preceding four weeks; of these, 192 resulted from whooping-cough, 66 from measles, 46 from diarrhœa, 39 from scarlet fever, 34 from diphtheria, 8 from "fever" (principally enteric), and one from small-pox. The lowest zymotic death-rates were recorded in Brighton, Norwich, and Bradford, and the highest in Oldham, Wolverhampton, Swansea, and Blackburn. The greatest mortality from measles occurred in Swansea, Sunderland, and Liverpool; from scarlet fever in Swansea; from whooping-cough in London, Oldham, Sheffield, Bristol, Wolverhampton, and Blackburn; and from diarrhœa in Swansea and Preston. The mortality from "fever" showed no marked excess in any of the large towns. The 34 deaths from diphtheria included 18 in London, 3 in Sheffield, 2 in Manchester, and 2 in Newcastle-upon-Tyne. One fatal case of small-pox was recorded in Oldham, but not one in any other of the large towns; 8 small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and 1 in the Highgate Small-pox Hospital on Saturday last. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of last week was 1244, against numbers declining from 1397 to 1274 at the end of the preceding three weeks; 117 new cases were admitted during the week, against 100 and 101 in the previous two weeks. The deaths referred to diseases of the respiratory organs in London, which had been 1465, 1192, and 761 in the preceding three weeks, further declined last week to 560, but were 45 above the corrected average. The causes of 92, or 2·0 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Croydon, Portsmouth, Bristol, Norwich, Sunderland, and in seven other smaller towns; the largest proportions of uncertified deaths were registered in Birmingham, Preston, Sheffield, and Sunderland.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 27·2, 24·7, and 22·0 per 1000 in the preceding three weeks, further declined to 20·8 during the week ending Feb. 13th, and was 2·3 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 15·1 in Edinburgh and 17·1 in Leith, to 27·2 in Greenock and 30·9 in Perth. The 578 deaths in these towns included 22 which were referred to whooping-cough, 10 to diarrhœa, 6 to measles, 4 to scarlet fever, 3 to "fever," 1 to diphtheria, and not one to small-pox. In all, 46 deaths resulted from these principal zymotic diseases, against 41 and 55 in the preceding two weeks. These 46 deaths were equal to an annual rate of 1·7 per 1000, which was 0·3 below the mean rate last week from the same diseases in the thirty-three English towns. The fatal cases of whooping-cough, which had been 16 and 20 in the preceding two weeks, further rose last week to 22, of which 11 occurred in Glasgow and 6 in Aberdeen. The 10 deaths referred to diarrhœa showed a further increase upon recent weekly numbers, and included 4 in Glasgow. The 6 fatal cases of measles were within one of the number in the preceding week, and were all recorded in Glasgow, where 2 of the 4 deaths from scarlet fever also occurred. The fatal cases of diphtheria, which had been 4 and 10 in the previous two weeks, declined to 1 last week, which was registered in Glasgow. The deaths referred to diseases of the respiratory organs in these towns, which had declined in the preceding three weeks from 230 to 173, further fell last week to 146, but slightly exceeded the number in the corresponding week of last year. The causes of 41, or more than 7 per cent., of the deaths last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 54·1, 41·5, and 33·6 per 1000 in the preceding three weeks, further declined to 31·8 during the week ending Feb. 13th. During the first six weeks of the current quarter the death-rate in the city has averaged 40·0 per 1000, against 35·8 in London and 20·9 in Edinburgh. The 213 deaths in Dublin during the week under notice showed a decline of 12 from the number in the preceding week, and included 3 which were referred to whooping-cough, 1 to measles, 1 to "fever," 1 to diarrhœa, and not one either to small-pox, scarlet fever, or diphtheria. In all, 6 deaths resulted from these principal zymotic diseases, equal to an annual rate of 0·9 per 1000, the zymotic death-rate during the same period being 2·2 in London and 0·6 in Edinburgh. The fatal cases of whooping-cough, which had declined in the preceding three weeks from 10 to 2, rose again to 3 last week. The death referred to "fever" corresponded with the number in the previous week, and was certified as enteric fever. The 213 deaths in Dublin last week included 29 of infants under one year of age, and 73 of persons aged upwards of sixty years; the deaths of infants showed a slight increase, while those of elderly persons showed a further decline from the high numbers recorded in recent weeks. Six inquest cases and 8 deaths from violence were registered; and 59, or more than a third, of the deaths occurred in public institutions. The causes of 14, or nearly 7 per cent., of the deaths in the city last week were not certified.

Correspondence.

"Audi alteram partem."

THE GRESHAM UNIVERSITY.

To the Editors of THE LANCET.

SIRS,—In your leading article of last week you referred to a quotation, or supposed quotation, from a speech of mine, with the perfectly justifiable remark that any words of mine were merely the expression of a personal opinion, and therefore, of course, unimportant in the discussion of a question of medical education. But I am not disposed to sit down under the false imputation of having said a foolish thing, and of having injured a good cause by my folly.

In a document put out by an anonymous committee sitting at the Outer Temple, with Mr. C. S. Roundell of Merton College, Oxford, for chairman, and Mr. J. S. Hill, of the Chelsea Branch of the London University Extension Association, for Secretary, after stating that "there is every reason to fear . . . the standard of degrees in the Gresham University will be unduly lowered," this committee without members, whose chairman and secretary are alike unknown to University education and to medical education in London, proceed as follows: "These apprehensions are confirmed by the official utterances of prominent promoters of the scheme, who have not hesitated to purchase the coöperation of the medical schools by the ominous suggestion that the mere qualification granted by the General Medical Council shall also qualify candidates (*per saltum*) for the Albert M.D. degree."

The use of the cant phrase *per saltum* shows that reference is made to my speech at the Westminster Hospital Medical School, which was (very imperfectly) reported in *The Times*, and still more imperfectly quoted—I might say garbled—in the *Quarterly Review*. To all I said I adhere.

In the case of students now studying in the medical schools who have satisfactorily performed a part of their course, I should rejoice to see, and I believe there will be no legal difficulty in providing, that they should have access to degrees in the Gresham University without being compelled to begin their students' course over again. This, however, must be subject to their giving satisfactory evidence of scientific and general attainment. Further, seeing that all students will be compelled to obtain a qualification outside the University at or about the time when they would, if the degrees conferred a qualification, be going in for an M.B. degree, I think it would be well for the medical authorities to consider whether they may not with advantage dispense with the M.B. degree altogether, and allow licentiates to proceed to the M.D. degree, as has sometimes been the case in other universities, *per soltum*. That the standard of the M.D. should in this way be lowered I have not proposed, and am sure it would be scouted by the authorities I was addressing, as such a proposal would deserve. That I said the mere qualification should also qualify for the M.D. degree is an entire mistake.

I am, Sirs, yours truly,

Whitehall, S.W., Feb. 17th, 1892. GEORGE YOUNG.

POST-MORTEM APPEARANCES OF THE BRAIN OF INFLUENZA PATIENTS.

To the Editors of THE LANCET.

SIRS,—With your permission I will briefly state the results of post-mortem examinations of the brain made at the West Riding Asylum in cases of influenza, in order that they may be compared with those quoted by Dr. Althaus from a Danish medical periodical. The morbid conditions described by the Danish observer and dwelt upon by Dr. Althaus in his letter may be summarised as follows:—(1) Hyperæmia at the base of the brain, arteries at base filled to bursting; (2) a most intense hyperæmia of the pia mater and brain; (3) increased consistence of brain and spinal cord; (4) fresh pachy- and lepto-meningitis. In addition, Dr. Althaus infers from the description that intense congestion of the medulla existed. During the spring and early summer of last year the brains of thirteen cases dead of influenza and its pulmonary complications were examined here. The results may be stated as follows, with strict regard to the morbid conditions specified above: 1. The arteries at the base are described as "healthy," "normal," and "atheromatous"; there is no mention of congestion. It is quite improbable that congestion in a remarkable degree should have escaped notice and record. 2. In two cases the "internal membranes" are described as "congested," in one as "perhaps congested." In two others it is stated that the pia contained but little blood. In the remaining cases the lepto-meninges were either normal or showed the changes of chronic brain disease (thickening, opacity). As regards hyperæmia of the brain itself, one case showed "much injection of grey and white matter throughout," and "the internal capsules were notably injected." In another the grey matter was "slightly congested." In a third the white matter was "congested in the posterior part of the brain." In two other cases the brain is described as "pale." In the remaining cases the colour was the average. 3. There is no note of increase in consistence in any of the cases; in nine the brain is said to have been of "reduced consistence." 4. No pachy- or lepto-meningitis in any of the cases. Lastly, if we take (as Dr. Althaus does) the state of the arteries at the base of the brain as a criterion of the vascular condition of the medulla oblongata, it may be inferred that no congestion existed in this organ in these cases, an inference which may be drawn with the greater confidence in view of the fact that the bulb is invariably examined in every necropsy held here. It is therefore extremely improbable that noteworthy congestion would have escaped detection. Apart from the testimony of the records, I am informed by my colleagues, who made the examinations, that they have no recollection of remarkable hyperæmia in any of these cases, whether at the base of the brain or elsewhere. I am, Sirs, yours faithfully,

EDWIN GOODALL, M D Lond., B.S., M.R C.P.,
Pathologist, West Riding Asylum, Wakefield.

Feb. 15th, 1892.

DEATH UNDER ETHER.

To the Editors of THE LANCET.

SIRS,—I beg to forward the particulars of a case of death under the influence of ether, which occurred on Jan. 29th at the Royal United Hospital, Bath. On Jan. 27th I admitted into the hospital, under the care of Mr. Freeman, S. D——, aged thirty-seven, a dustman, who was suffering from a small strangulated right inguinal hernia. He had attended as an out-patient at the hospital on the previous day (and was seen by one of the honorary assistant medical officers), complaining of symptoms which appeared to be due to his drinking habits, he making no mention of the rupture. The patient, although very weak, walked to the hospital on the day of admission. He was placed in bed and the usual measures for taxis were employed; but, these proving unavailing, and his general condition becoming rapidly worse, he was given an enema of brandy, and taken to the operating theatre for the purpose of performing herniotomy. On examination no sign of organic lesion was discovered in the chest, and ether was slowly administered by myself. There was some struggling at the commencement, but anæsthesia was induced in from six to eight minutes, and the operation was begun by Mr. Freeman. Two minutes later breathing ceased (the temporal pulse persisting), after three or four shallow respirations. There was no stertor or mydriasis. The tongue was immediately drawn forward, the head thrown back, and artificial respiration performed, enemata of brandy and injections of strychnia being given and the faradaic current employed to the phrenic nerves. A few ounces of dirty bilious fluid escaping from the mouth soon after, tracheotomy was performed to obviate the risk of any foreign matter being sucked into the lungs. Although artificial respiration was continued for an hour and a half, all efforts to resuscitate the patient were ineffectual, no signs of vitality being noted after the cessation of breathing. A post-mortem examination was made by myself thirty-six hours later. Rigor mortis was marked. On opening the hernial sac a small knuckle of ileum was alone seen. This was very deeply congested, but the congestion did not extend to the mesenteric border, involving only about two-thirds of the circumference of the gut. The bowel was adherent to the sac round the neck, and there were a few flakes of recent lymph on the abdominal side of the ring. Beyond a few atheromatous patches on the aorta above the sigmoid valves and slight

Digitized by Google

marginal emphysema, no abnormal appearance was detected in any of the organs of the body.

I am, Sirs, yours obediently,
E. H. BIDDLECOMBE, M.B Lond.,
Resident Medical Officer, Royal United Hospital, Bath.
Feb. 15th, 1892.

THE ASSOCIATION OF DIPLOMATES AND STUDENTS OF THE LONDON MEDICAL SCHOOLS AND THE PROPOSED GRESHAM UNIVERSITY.

To the Editors of THE LANCET.

SIRS,—I am sending you a parchment skin with print of petition attached which you have kindly consented to place in your office for signature by diplomates and students of the London medical schools interested in the movement. May I ask you to be good enough to allow me to announce through the medium of your columns that the original petition is, by consent of the President of the British Medical Association, placed in the Library of the Association at No. 429, Strand, and that other parchment skins have been sent to the deans of the various London hospitals for signature by students and resident diplomates. My committee have found it impossible to send the original petition from house to house, and they trust that the diplomates will so far consult their own personal interests as to put themselves to the slight trouble of calling to sign the petition at one of the places where the skins are left.

I am, Sirs, yours faithfully,
ERNEST W. GREENWOOD, Hon. Secretary.
Serjeants' Inn, Temple, Feb. 17th, 1892.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

The Hospitals.

DURING the past week or two many of our local medical charities have held their annual meetings, and, unfortunately, with the majority of them financial difficulties are the rule, income and expenditure balancing on the wrong side. At the Children's Hospital a good year's record of work was presented. In the out-patient department 10,571 cases have been treated; whilst the number admitted as in-patients was 1249, the average cost of these latter being £5 18*s.* 9*d.* The reputation of the hospital as a training school for nurses is maintained, 280 applications for admission to the nursing staff having been received during the year. The total expenditure had been £7330, and the ordinary income from subscriptions &c. had fallen £1000 below this amount. Mr. Oliver Heywood, who for many years has been one of this hospital's warmest supporters, foreshadowed the possibility in the near future of some application of public moneys to the support of medical charities, and the Mayor, in his speech at the meeting, more than hinted at the same thing. As a Bill has been introduced into the Commons this session having for its object this very proposal, it is possible public attention may be directed to the matter of rate support to hospitals.—The Hospital for Skin Diseases (which was originally an off-shoot of the Lock) wants to extend its work by providing accommodation for in-patients, and the committee are doing their best to obtain funds for this purpose.—The report of the managers of the Eye Hospital was the exception to the rule; for, without any diminution of efficiency, they were able to point to a balance of £957 in excess of expenditure. They referred with gratitude to the support they receive from the adjoining districts and places outside Manchester, from whence, as with most of our other hospitals, so many of the patients come. Nearly 18,000 out-patients and 1241 in-patients is the record of the year's work here in bald figures.—The Clinical Hospital for Women and Children had its annual meeting, presided over by the Bishop, and the only unsatisfactory item of its report was the adverse financial one. The report showed a deficiency of £1625, and, unless help be forthcoming, the work of the charity will have to be curtailed. Here again Mr. C. Schwann, M.P., who moved a vote of thanks to the staff, alluded to the possibility of support being given from the rates for public hospitals, and expressed himself as being of the same opinion as the Mayor in this respect.—The eighth annual meeting of the Dental Hospital was held yesterday. Up to the present only out-patients have been dealt with, the present accommodation not permitting the treatment of in-patients. The committee appeal for funds to provide a new building, in which the latter can be received. They have procured a suitable site from moneys received from the late Mr. Procter, by whom so many other Manchester charities have been helped, and hope at an early date to have funds sufficient to commence building operations. Last year 12,072 patients were treated, a considerable number of whom were attended in the evening, thus preventing loss of time to poor people engaged at work during the daytime.—At the annual meeting of the Blind Asylum a very discordant note was struck. This institution contains 170 patients, and usually pursues the useful tenour of its way without attracting much public attention. This year, on submitting the minutes for confirmation, a proposal to advance the secretary's salary by £50 was opposed by Messrs. Hobbs and Helm, both of whom have taken an active part in the management. The proposal was, however, adopted by the meeting (which was a comparatively small one); but when the names of the members of the Board for the ensuing year were before the meeting these two gentlemen were blackballed and others substituted. This action has caused much adverse criticism, especially as Mr. Helm is known throughout the city as a warm-hearted philanthropist, helping in the work of more than one local charity with his time, energy, and money.

Hospital Sunday.

Sunday last was set apart as Hospital Sunday, and Saturday next will be Hospital Saturday. This is the twenty-third time in which funds have been raised in this manner for the hospitals here. Last year upwards of £8800 was obtained. Sunday last was, unfortunately, a wet day, and not propitious for the occasion. The committee appeal strongly this year for assistance from the numerous towns and districts which furnish so many of the patients to our hospitals, though many of these have of late years either erected or enlarged their own local hospitals.

Town Refuse.

Suburban districts, like cities, are getting the problem of disposal of their refuse prominently thrust upon them. The Withington Local Board, whose township borders closely on us, has been making application to borrow money for the erection of a destructor, but was opposed by one of our boards of guardians on the ground that the site was in too close proximity to their workhouse. Seeing, however, that the distance therefrom was between three and four hundred yards, and that many towns have them working, apparently without nuisance, in the midst of dwelling-houses, the opposition appears scarcely called for.

Drink or Apoplexy?

It sometimes happens that the police are blamed for keeping persons locked up in a cell as drunk when the unfortunate individual has been suffering from cerebral hæmorrhage. The difficulty which is at times experienced in diagnosing these cases has received an unfortunate illustration recently. A man who had been drinking and fighting was taken to the infirmary with a scalp wound. After being dressed he was sent away in charge of the police, who locked him up as drunk, but shortly afterwards brought him back to the infirmary by order of the inspector, who thought him suffering from something more than drink. He was again examined by the house surgeon, together with another resident officer, who both failed to detect any symptoms of serious injury, and he was again sent back to the police cells. The following morning he was admitted to the infirmary in an unconscious condition, and died a few hours afterwards. At the post-mortem examination was discovered a fracture at the base of the skull, with extensive hæmorrhage into the brain.

Medical Scholarship.

Slowly year by year the number of prizes and scholarships in the medical department of the college are increasing. Under the will of the late Mr. Henry Agnew £1000 is provided to found another medical scholarship. By the same will the Children's Hospital benefits to a like amount.

Influenza &c.

Hitherto we have escaped the prevailing epidemic fairly well. Four or five deaths a week the last month is the sum total of the mortality caused by it, and at present there are

Digitized by Google

no signs of any serious extension. The death-rates of both Manchester and Salford have of late been below our usual average. The carelessness of the public, or some sections of it, with regard to infection had an illustration last week, when a man was summoned and fined for taking the dead body of his child (who had died from scarlet fever), enclosed in a coffin, by passenger train from Manchester to Macclesfield, the coffin being placed in an ordinary third-class compartment.

Manchester, Feb. 16th.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

Newcastle Dispensary.

FROM the report read at the annual Court of Governors of the Newcastle Dispensary, the Mayor in the chair, it appeared that 8378 letter patients and 15,355 casuals had been treated during the past year. The financial state of the institution was satisfactory. The receipts amounted to £8200, and the ordinary expenditure to about £3000, so that there was a substantial balance in hand. The committee, having regard to the strong financial position of the institution, felt that they would be carrying out the wishes of the founders and aiding the recovery of the patients if provisions for establishing a convalescent home were made, or arrangements entered into so that patients could be sent to some such home. The Mayor suggested that, having regard to the size of the city, a dispensary might be placed at each end, which would relieve the patients and their friends, who at present had to travel a long way to the Central Dispensary.

North of England Microscopical Society.

At a meeting of this Society held last week in the Hancock Museum, Newcastle, Mr. R. Ellis, F.R.C.S. Ed., in the chair, Mr. G. E. Williamson, F.R.C.S., gave a demonstration of the methods of preparing animal tissues for the microscope microtomes of American and other designs capable of cutting with rapidity and accuracy to the ten-thousandth part of an inch in thickness. A portion of the retina of the human eye, having been embedded in paraffin, was thus cut. Mr. Williamson also showed practically how the paraffin and xylol method, besides supplying the requirements of a large class of students, could be modified to serve as a quick and reliable guide to the surgeon in the diagnosis of diseased tissue.

Malton Dispensary.

The annual meeting of the Malton Dispensary has been held, and the report showed that the institution was working very efficiently, and its benefits had been fully appreciated by the poor. A sum of £600, which was left by the late Mr. Beckett, had been invested, and there was a balance in hand on the year's working of £15 8*s*. Since the opening of the dispensary nearly 18,000 patients had been treated.

Newcastle Health Society.

Dr. Hume inaugurated the second session of the Newcastle Health Society on the 6th inst. by a lecture on the Human Foot and Foot Clothing. Dr. Hodgkin presided, and the theatre of the Literary and Philosophical Society was crowded. The complex and beautiful structure of the foot was illustrated by limelight views.

Influenza in the Northern Counties.

I think there is a general subsidence of the influenza epidemic in the Northern Counties, where its ravages have been very serious. The medical officer of the Northallerton sanitary authority has reported that it prevailed in the district during the whole of January, and has materially increased the death-rate, particularly amongst the aged. In the Normanby district of Middlesbrough the death-rate is still reported as exceptionally high. Dr. Glen states that this is not to be wondered at when the vast numbers of persons who were stricken with influenza is considered, the disease in many cases being complicated with some chest affection. Towards the end of last month he says there was a marked decrease in the number of cases of influenza, but several cases of measles were observed in the northern part of the district. In the Whitby district and various parts of North Yorkshire a grave form of pneumonia has been prevalent, and the medical practitioners have been fully occupied. I hear, however, that lately the attacks have been less numerous and not so severe.

Darlington: the Nursing Difficulty.

At a late meeting of the Darlington Guardians Dr. Drury stated that the greatest difficulty had been found in treating the poor and the class above the poor, owing to their ignorance of nursing. As showing the want of practical knowledge which prevailed, he instanced the use which had been made of the beef supplied to the poor for the purpose of making beef-tea. The liquid, he said, resembled water, whilst the meat, which had been boiled in large chunks, was put into a pie.

Berwick: the Improvement of Spittal.

A movement is on foot by the Berwick sanitary authority to improve the village of Spittal, the watering-place and suburb of Berwick. Spittal, which derives its name from a leper hospital founded here by Edward I., is a place of considerable natural attractions. It has already some good hotels and lodging-houses, and a mild chalybeate spring—the spa well, once in considerable repute in scorbutic and allied affections. It is proposed to publish the analysis of this spring and to borrow £1000 from the Local Government Board to replant the main street with trees and to improve the sewerage. In former times Spittal fishermen were much addicted to smuggling, and it was one of the most noted places on the coast for landing contraband goods. In the old houses were secret holes and nooks made to stow away a whole cargo. In some instances the soil underneath the kitchen floors was entirely removed to form places of concealment for kegs of brandy and gin and bales of tobacco.

I regret to hear that the accounts of Dr. Heath's health are not so satisfactory this week.

Newcastle-on-Tyne, Feb. 17th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Royal Edinburgh Hospital for Sick Children.

THE annual meeting of the contributors to this hospital was held on Feb. 12th. In the report submitted to the meeting it was pointed out that the distance from town of the building at present used was somewhat against patients finding their way to it, and that the dispensary work had been carried on at considerable disadvantage. The number of patients treated in the wards during the year was 571, the number at the dispensary 6054, and the number of vaccinations 111. The number of patients treated since the hospital had been instituted was 173,770. The income for the year was £5044, being a considerable increase over the preceding year, and the expenditure was £6047, which, however, included special outlay on their present premises. The legacies showed a considerable falling off. Reference was made to the negotiations with the Royal Infirmary; but as these had fallen through, the directors had decided to rebuild the hospital on the old site, and the architect had prepared plans which had been approved by the Board. They had been requested to confer again with the Royal Infirmary managers, and they would of course be glad to meet them, and to talk over the possibility of mutually satisfactory arrangements being made if practicable. Intimation had recently been received by the directors of several large benefactions; one of these was a gift of £10,000 from Lady Jane Dundas, in memory of her sister, Lady Caroline Charteris. Half that sum was to be expended under special arrangements on the new building, the design for which the donor has seen and approved, and the other half was to be devoted to the perpetual endowment of ten beds in the hospital.

Health of Edinburgh.

The mortality last week was 75, and the death-rate 15 per 1000. Diseases of the chest accounted for 30 deaths, and zymotic diseases for one. The intimations for the week were: Typhus fever 1, typhoid fever 1, diphtheria 3, scarlatina 18, and measles 92.

The Universities Commission.

The commissioners have just issued four ordinances dealing with the following: Regulations for degrees in medicine (Ordinance 16); regulations for degrees in arts (Ordinance 11); regulations for degrees in science (Ordinance 12);

Digitized by Google

and regulations as to examinations (Ordinance 13). The points of interest in these bearing upon the medical curriculum and examinations will be referred to fully next week.

Edinburgh Royal Infirmary Extension.

On Monday a conference took place between a deputation of the managers of the Royal Infirmary and the directors of the Sick Children's Hospital with reference to the proposed acquisition of the site of the latter for the extension of the Royal Infirmary. The agreement come to was that the managers of the Royal Infirmary should make a definite proposal to the directors of the Sick Children's Hospital with reference to the acquisition of the property.

Aberdeen Hospital for Sick Children.

The report for last year submitted at the annual meeting of the subscribers and friends of the Children's Hospital shows that during the year 555 patients were treated in the wards, as compared with 484 in 1890. Of the 555 patients, 346 were cured; 84 improved; 42 unfit; 31 died, and there were 50 in the wards on Dec. 31st. Of ophthalmic cases 94 were treated in the wards, and there were 43 out-patients. The dental operations during the year numbered 52. In the out-door department there were 757 cases treated. It is noted that of the fatal cases 6 died within twenty-four hours of admission. The convalescent cottage, known as the Eidda Home, was open from June 3rd to Oct. 30th, and during that time 47 children had the benefit of several weeks' stay in the country, and 9 more were received into Dyke Neuk Cottage—a convalescent home also situated on Deeside a few miles from the city, and under private management. The increased number of patients means a proportionately larger expenditure for the year, which was £2001 2*s.* 2*d.* as compared with £1717 8*s.* in 1890; and the accounts for the year show a deficit of £101 2*s.* 8*d.* At the end of 1890 the debt on the hospital was £1670 5*s.* 7*d.*; but during the year legacies and donations were received amounting to £2374 10*s.*, and the available portion of this sum has reduced the debt to £716 7*s.* 11*d.*

The late Dr. J. W. Hutchem.

In his report on the health of the city of Aberdeen, submitted to the Town Council on Monday, Dr. Hay says: "It is with very painful feelings that I allude to the death from influenza, during the month, of Dr. J. W. Hutchem, my medical assistant for the past three months at the hospital. Dr. Hutchem was greatly esteemed by myself, the matron, the nursing staff, and the patients, alike for his high personal qualities, his professional ability, and the faithfulness of his services.'

Health of Aberdeen.

The death-rate continues high; that for the present month exceeds the average of the last ten years by nearly 30 per cent. For the last week it was over 29 per 1000. During the week five deaths from influenza were recorded.

Seizure of Unwholesome Food.

During the month of January the sanitary inspector seized as unfit for human food 1746 lb of beef, 38 lb. of mutton, 12 lb. of potted meat, and 1946 lb. of fish. At the police-court, on Saturday, 13th inst., two farmers were each fined £5, with 16*s.* 3*d.* of expenses, for having in their possession or owning two parcels of beef which was intended for human food, and was unfit for such purpose.

Professor Grainger Stewart is now rapidly recovering from his attack of influenza, and is expected to be able shortly to resume his professional duties.

Feb. 16th.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Royal College of Surgeons in Ireland: the New Schools of Surgery.

THE new schools which have been built in connection with the Royal College of Surgeons were formally opened by the president of the College, Mr. Croly, a few days since. The schools constitute a new wing at the rear of the College, and include a dissecting-room, a smaller dissecting-room for lady students, a chemical laboratory, and a lecture theatre. The School of Surgery of the College was established in the year 1790, and in the following year the Government gave a grant for its improvement. In 1811 a further grant of £2000 was made by the Government for the same purpose. The school buildings were gradually enlarged, and in 1882 a sum of £3500 was expended by the College in further improvements. In 1885 the school was opened to lady students, many of whom have since passed with distinction for the licence. In 1889 the Carmichael School of Medicine, which had been in existence from 1826, and the Ledwich School of Medicine, which was established in 1836, were amalgamated with the College of Surgeons School. This necessitated increased accommodation, and last year the College resolved upon the construction of the building, at a cost of £5000. The principal dissecting-room, which accommodates 400 students, is seventy-four feet in length, by sixty-four wide and about twenty-two in height. The roof, of which the central portion is higher and is glazed, is supported by metal columns and beams; it is composed of asphalted concrete, and is fireproof. The floor is of concrete asphalted, and is also fireproof. The ladies' dissecting-room is about thirty feet square. The chemical laboratory is sixty-four feet by twenty-eight. It is already filled with chemical appliances, and has been used in connexion with the chemical lectures during the last few days. Dissecting tables of teak extend round the walls of the principal dissecting-room, and the ladies' dissecting-room is also fitted with teak tables. All the rooms are provided with electric lamps, and are heated by a system of hot-water pipes. There is also a bone-room, in which specimens of human bones are preserved for purposes of study, and a lift extends through the rooms by means of which the subjects are raised from a cellar below, where they undergo a process of preparation before being used for dissection. Mr. H. Gray Croly, President, will give a banquet on Monday evening, March 14th, at the College, to celebrate the first biennial presidency of the College. His Excellency the Lord-Lieutenant has accepted Mr. Croly's invitation to be present.

Irish Dispensary Medical Officers.

A conference to consider the grievances of dispensary medical officers in Ireland was held on Wednesday at the College of Surgeons. Representatives of the Irish and British Medical Associations, the Irish Graduates' Association, and also delegates from various meetings held by Poor-law medical officers were present. The three chief requirements for the present medical officers of dispensaries would appear to be compulsory superannuation, increase of salaries, and some modification of the visiting ticket system.

Proposed Hospital for Consumption.

Opinions are divided as to the necessity for an institution for phthisical patients near Dublin. It is pointed out that to add another hospital to those already existing would be very unwise, and would add another tax on the charitable public, already overburdened with appeals. It is suggested that instead of a separate hospital for consumption being erected at an enormous expense, which would require several thousands of pounds annually to keep it up, additional wards might be erected in connexion with the Royal Hospital for Incurables, which could be carried out and endowed at a comparatively moderate expenditure. A meeting of the promoters will be held this week to consider the matter.

Green-street Court-house.

The Lord Chief Justice last week, in addressing the Grand Juries of the City and County of Dublin, spoke in strong terms in reference to the insanitary condition of the court-house. He said he did not know who was responsible for this condition of things. If it was the Government who were to blame, it was a disgrace to them, and the same would apply to the Corporation. The place was pervaded by a mephitic atmosphere, and exhalations which proceeded from beneath the floor of the courthouse were pestiferous, and sometimes absolutely overpowering. His lordship said that if he did not find before the next Commission that some practical move had been taken to remedy the state of things, he would summon a meeting of the common law judges and take counsel with his brethren on the bench as to whether they could not go elsewhere. The disgraceful condition of this courthouse has on numerous occasions been referred to in these columns, but redress seems as far off as ever. If the Government, who are primarily to blame, would subscribe handsomely, the Corporation and the citizens would undoubtedly help to erect a proper courthouse in place of the present inconvenient and dangerous structure.

University of Dublin: Tercentenary.

It is contemplated to establish a graduates' memorial of the tercentenary, to take the shape of a building in which

Digitized by Google

the various College societies can be accommodated. A meeting of those interested in the movement took place on Tuesday, and was presided over by Lord Rosse, Chancellor of the University. Already some 6000 circulars have been issued to graduates of the University, both at home and abroad, and the replies already received have given convincing proof that a fund will be obtained which will be ample for the proposed project.

Health of Dublin for the Last Quarter of 1891.

During the December quarter the births registered in the Dublin Registration District numbered 2133, or 24·6 per 1000, and the deaths 2584, or 29·8 per 1000, being 2·4 above the average for the fourth quarter of the past ten years. Zymotic diseases caused 335 deaths, or 109 over the number for the preceding quarter, the increase in the mortality being principally due to the prevalence of enteric fever, which caused 105 deaths, being 54 in excess of the average for the corresponding quarter of the last ten years. There were only 4 deaths registered from typhus fever. Whooping-cough caused 48 deaths, influenza and its complications 32, measles and scarlatina 2 each, and diarrhœa and dysentery 83. To deaths from diseases of the respiratory system were due 626.

Ulster Eye, Ear, and Throat Hospital.

The twenty-first annual meeting was held on Feb. 15th, and from the report I learn that 1515 patients were treated during the year, of whom 179 were intern. The committee urge the need of extension of the premises, and state that, with £600 in addition to the £400 they have in hand, they could undertake the desired addition. Owing to the fact that in order to put the public and private departments of the hospital in the best condition a considerable sum of money has been spent, the debt has increased to £130 12*s.* 5*d.* The total receipts for the past year amounted to £542 15*s.* 9*d.*, and the total expenditure to £647 19*s.* 11*d.*, of which £91 8*s.* 11*d.* was for furnishing. In the medical report I gather that some fifty-two operations for cataract were performed in the past year without the loss of a single eye. Clinical instruction has been given to a class of students of the Belfast Medical School, in accordance with the regulations of the Royal University, and the most perfect scientific appliances are being provided for demonstration and instruction.

Belfast Hospitals.

On Feb. 15th Captain M'Calmont, M.P., asked the Chief Secretary in the House of Commons whether, in consideration of the fact that a sum of close upon £16,000 is voted annually by Parliament for the maintenance of hospitals in Dublin, he would be prepared to recommend that an annual grant should also be made to similar institutions in Belfast, which are of necessity supported entirely by voluntary contributions. In his reply, Mr. Jackson, M.P., said he was not aware of any proposal to make grants from public moneys to the hospitals in Belfast or any other cities of the United Kingdom. Nor did he think, if such a proposal was made, that it would meet with the approval of the House. It is felt in Belfast that Dublin has no special claim whatever to this grant. Belfast now pays a larger sum to the Imperial revenue than does Dublin, and the mere argument that custom or prescription gives a right will not stand in these days. It is also urged that Dublin has a metropolitan title. Then, again, in the question of population, Belfast is now as large; indeed, some authorities say it is larger than Dublin. In commerce it is far away the leading city of Ireland, and it can hardly be urged that the Dublin hospitals are, as compared with those in Belfast, entitled to be called metropolitan. It is quite evident that this subsidising of the Dublin hospitals out of the Imperial exchequer is an anomaly which will have to be done away with sooner or later.

Mr. Thomas George Stevens, L.R.C.P.I. &c., has been appointed Assistant Medical Superintendent of Dundrum Criminal Lunatic Asylum.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Treatment of Pneumonia following Influenza.

IN these days of influenza, in which disease pulmonary complications are so common, the opinion of such a competent therapeutist as M. Huchard on the treatment of these complications may be worthy of transcription. That authority (Soc. de Thérapeutique, Feb. 10th) reminded his audience that the pneumonia observed amongst sufferers from the prevailing epidemic assumed various types. In some, the pneumonic fever belongs to the ordinary fibrinous variety, the characteristic micro-organism being the pneumococcus. In another class of cases we meet with bastard pneumonia, in the non-rusty expectoration of which we find the streptococcus. This kind of pneumonia is apt to relapse more than once. Other varieties of pneumonia are those characterised by (*a*) rapid evolution with purulent expectoration; (*b*) pulmonary collapse, or "massive" congestion of the lung with gummy expectoration; (*c*) abundant subcrepitant râles without a souffle, death occurring from dyspnœa and adynamia. Empyema or pulmonary gangrene may be superadded, and bring about a fatal result. In all these forms the dominant factor is the state of nervous asthenia in which the patient is plunged, and, consequently, all modes of treatment should be directed less to combat the actual pulmonary lesion than to sustain the action of the heart, and, in a subsidiary degree, encourage the elimination of the toxines through the renal filter. This double object is attained by the administration of digitalis given from the very commencement concurrently with an exclusively milk diet. M. Huchard has for a long time discontinued the employment of the infusion of foxglove, preferring crystallised digitalin in a solution of 1 in 1000. Of this solution he administers forty or fifty drops (equal to one milligramme of the alkaloid) once a day for the first two days. Should the prostration be profound hypodermic injections of caffeine, ether, or camphor (in solution of 1 in 10 in sterilised olive oil), twice or oftener a day. If within a week a resumption of this digitalis treatment be indicated, half of the above dose is given. Intestinal and buccal antisepsis is also given a prominent place in the treatment, five or six *cachets* a day of fifty centigrammes each of benzonaphthol being relied on for the one, and a mouth-wash of corrosive sublimate for the other. Should the caffeine, ether, or camphor prove insufficient remedies for the asthenia, M. Huchard has recourse to subcutaneous injections of sulphate of strychnia two or three milligrammes a day. In all cases the treatment is completed by the daily exhibition of one or two teaspoonfuls of a mixture composed of equal parts of tincture of kola and tincture of coca, the vehicle employed being either a cup of hot milk or diluted curaçao.

Lady Students in Paris.

From a report just issued I learn that the number of ladies pursuing their studies at the various faculties of Paris has increased from 152 in the year 1890 to 252, the actual figures. An analysis of the nationality of these fair aspirants to academic honours tells us that at the Faculty of Medicine 18 are French, 6 English, 3 Roumanians, 2 Turks, 1 Greek, 1 American, and no less than 103 Russians. At the Faculty of Sciences there are 14 foreigners to 5 natives. At the Faculty of Letters, however, the French take their revenge, 82 out of 97 being *citoyennes* of the French Republic. Three ladies, all Russians, have graduated during the last year as Doctors of Medicine.

Erysipelas at a School.

It is not often that one hears nowadays of a school being evacuated on account of an epidemic of erysipelas. Such, however, has been the case recently at Vitry-le-François, where the pupils of the ladies' college have been sent to their respective homes from this cause. The *Progrès Médical* remarks very truly that such an occurrence as a serious outbreak of erysipelas should be an impossibility in these enlightened days.

Traumatic and Gastric Origin of Tachycardia.

Professor Le Dentu relates the following case in a recent number of the *Médecine Moderne*. A cabman, aged forty-nine years, fell off his box, and when picked up was found to have sustained an extensive scalp wound, with denudation of the skull. On the following day the patient had an attack of tachycardia (from 200 to 300 pulsations a minute), lasting about fifteen hours, the attack being preceded and followed by arhythmia and cardiac intermittence. There was only a trifling elevation of temperature (37·8° to 38·7° C.), and no cardio-vascular or cerebral signs or symptoms were observed. For some time previous to the accident the patient had suffered from palpitations, but there appears to be no reason to doubt that the above access was caused by the traumatism. Such a connexion

Digitized by Google

has not, to my knowledge, been pointed out before. With regard to the gastric origin of this distressing neurosis, a case recently treated by Dr. Barnard of Paris is very instructive. The patient was an American lady, aged about forty-two. She was found lying flat on her back, not daring to make the slightest movement. The cardiac pulsations were so rapid that their enumeration was almost impossible. There were no abnormal cardiac sounds, and the other organs were recognised to be healthy. The patient had suffered previously in the same way in her own country, and she had never derived benefit from any of the remedies, including digitalis, that had been administered, the attacks seeming to subside spontaneously. The remedies now successively tried were a belladonna plaster and an ice-bag over the heart, bromide of potassium, bismuth, and digitalis. Not the slightest benefit accruing, Dr. Barnard administered at 11 P.M. an emetic of twenty grains of ipecacuanha and one grain of tartar emetic. The vomiting brought the pulse down at once to 112, and the patient was left for the night, much relieved. On the following morning the pulse was 82, and the lady quite well. Dr. Barnard, I believe, was led to try an emetic in this case by a remark made by his patient to the effect that, in a previous attack occurring in London, she dated her recovery from the moment when, "in consequence of the nasty messes prescribed by her doctor," the stomach rebelled and expelled its contents.

Jacques Inaudi.

Poeta nascitur non fit. The feats of Jacques Inaudi at the Académie des Sciences last Monday week seem to prove that the above axiom is as applicable to arithmeticians as to poets. Inaudi is a native of Piedmont, twenty-four years old, and of short stature. The size of the head is rather below the normal standard, the forehead is very lofty and straight, and the facial angle well developed. That his calculating powers are of a very high order, and his memory something quite extraordinary, is proved by the following experiments performed before the assembled academicians. Facing the audience and consequently turning his back to the blackboard, M. Darboux writes on this latter the following figures: 4,123,547,238,445,523,831 and 1,248,126, 158,234,128,910, and, after having called them out, asks Inaudi to subtract the one from the other. Inaudi repeats the numbers quite correctly, closes his eyes firmly, and immediately answers correctly. M. Darboux then puts the following question: "What number is it whose square and cube added together equal 3600?" In less than two seconds Inaudi replies "15." M. Poincarré then gives the following problem: "Give the square of 4800, subtract one and divide by six." At the same time, M. Bertrand asks: "On what day of the week did March 11th, 1822, fall?" Inaudi replied immediately, "The 11th of March, 1822, was a Monday, and a person born on that day would have lived to-day, had he survived, so many hours, minutes, and seconds." (All these figures were found correct.) "The result of the calculation proposed by M. Poincarré is 1960." These astonishing feats of rapid calculation greatly surprised the scientific men present, and the Academy forthwith appointed a committee, composed of MM. Darboux, Poincarré, Charcot, Chauveau, and Tisserand, whose duty it will be to report on the mnemotechnic methods employed by this wonder of the nineteenth century. It is said that Inaudi can hardly read or write.

Paris, Feb. 17th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Treatment of Cancer.

IT is reported that several Berlin cancer patients have asked Professor Billroth of Vienna whether he would advise them to subject themselves to the treatment proposed by Professor Adamkiewicz of Cracow, and that Professor Billroth has answered that he has not yet seen any cancer patient cured by the treatment.

Rohrbeck's Disinfector.

A work which has been carried on for a long time past with great care and perseverance has now been finished. Its purpose was to clear up the numerous obscurities and contradictions that had come to light in the researches of various observers on sterilisation and disinfection. It was undertaken by Dr. Hermann Rohrbeck and H. C. J. Duncker, a veterinary surgeon in the service of this city. Their first endeavour was to find sure aids and means of control for the practical execution of the requirements that the articles to be disinfected must be interpenetrated by saturated steam of 100° C. It was possible to ascertain the heat in the inmost parts by means of electric contact-pyrometers, but the difficulty has hitherto been to determine the moisture there. Dr. Rohrbeck proved in 1889 that different kinds of steam possess different disinfecting powers, and that it is necessary entirely to remove the air from the articles to be disinfected if the steam is to penetrate them thoroughly. He constructed a disinfector which warrants the production of saturated steam and the complete elimination of the air. Duncker afterwards invented new electric pyrometers and hygrometers, which enabled one to observe the advance of the steam inwards step by step. It deserves special mention that the condensation of the steam in Rohrbeck's apparatus, with a view to removing the air, considerably increases the temperature of the articles to be disinfected.

Professor Virchow.

On the 9th inst. Professor Virchow addressed the following to one or more of the Berlin papers: "Cincinnati papers publish lengthy advertisements, according to which the 'great German physician,' Dr. Karl Virchow Schick, has arrived there from Berlin and opened his consultations. It is alleged that he has made important discoveries in the germinal treatment of chronic diseases, and that his prescription is used by 806 doctors in Europe. Permit me to remark that, according to the official lists, there is not and never has been a physician of this name in Berlin or in Prussia, and that such a one from the other states of the German Empire is also not known. It is hoped that this notice will suffice to induce the American papers to oppose the tactics of the gentleman in question."

Professor Franz König of Göttingen, an eminent German surgeons, celebrates his sixtieth birthday to-day.

Berlin, Feb. 16th.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The Coagulation of the Blood.

THE experiments of Dr. Ernest Freund of Vienna on the conditions which prevent the coagulation of the blood have been from time to time reported in the pages of THE LANCET. He has found that the non-coagulation of the blood in the living bloodvessels is due to the physical action of the walls of the vessel, and he has been able to preserve shed blood from coagulating for many hours or even days by contact with oily liquids and fatty matters, such as vaseline or oil. The blood could also be kept liquid in animal membranes or parchment paper tubes soaked in physiological solutions of common salt (½ per mil.). From these experiments he has come to the conclusion that the physical condition for coagulating the blood is adhesion. In his paper on "The Formation of the Phosphate of Lime as a cause of Coagulation," Dr. Freund has pointed out that coagulation of the blood is due to phosphate of lime being formed and becoming insoluble. His views have been confirmed to a great extent by Green, Ringer, Sainsbury, Haycraft, Pekel, and others. It has also been found by Arthus and Pagès that the blood remains liquid if the lime salts are made insoluble by the addition of a small quantity of oxalate of ammonium, and that the coagulation is then produced again by adding a solution of calcium chloride. These latter facts have been made use of by Dr. Wright in his recent experiments on blood transfusion. But while in the experiments of Arthus and Pagès and Wright the blood remained liquid on account of the formation of an insoluble lime salt, Dr. Freund has now found a substance which prevents the coagulation of the blood by keeping the phosphate of lime dissolved. By receiving the blood into a vessel containing small quantities of citrate of ammonium or of citrate of sodium it loses its coagulability, as has been shown by experiments made by Dr. Freund at a recent meeting of the Vienna Society of Physicians. In this case the phosphate of lime is kept dissolved by the action of the citric salt. Solutions of from 0·2 to 0·4 per cent. were used. By these experiments a new direction seems to be given for

Digitized by Google

working out practical problems like that of blood transfusion and of hæmostatic action.

Influenza.

According to the last official return the influenza is decreasing in Vienna, only 118 cases having been notified during the week from Feb. 7th to 13th. It is to be noted that the disease was raging more among the wealthy people than the poor.

Vienna, Feb. 16th.

THE SERVICES.

AS we announced some time ago, Surgeon-Colonel Bradshaw will, on promotion, succeed to the post of Principal Medical Officer of Her Majesty's Forces in India on the retirement of Surgeon-Major-General Thomson.

It is rumoured that Surgeon-Major F. W. Trevor is likely to be the successor of Surgeon-Major Rogers as Principal Medical Officer of the Egyptian Army. The latter officer becomes the head of the Egyptian Sanitary Service, a post vacated by Surgeon-Major Green Pasha.

Surgeon-Lieutenant-Colonel H. Comerford has been appointed Principal Medical Officer on the staff at the Curragh.

By the retirement of Brigade-Surgeon-Lieutenant-Colonel R. Collins the medical staff loses a very valuable officer of excellent judgment, common sense, and administrative capacity. Previously to joining the Woolwich garrison this officer was stationed at Gibraltar, where he acquired considerable reputation by his sound professional knowledge, kindly disposition, and readiness to help everyone.

ARMY MEDICAL STAFF.—The undermentioned Surgeons on probation to be Surgeon-Lieutenants (dated Jan. 30th, 1892):—Edgar Montagu Pilcher, M.B., Henry Percival Johnson, William George Bevts, Harold Arthur Stalkartt, M.B., Henry Nason Dunn, M.B., Samuel Henry Withers, M.B., Edwd. Maudsley Morphew, Ernest Chester Anderson, Nicholas Tyacke, Robert Hughtrede Edward Holt, Lionel Arthur Mitchell, M.B., Charles Christie Fleming, M.B., John Hennessy, M.B., Claude Buist Martin, M.B., George Johnstone Buchanan, M.B., Charles Bunbury Lawson, M.B., George Edgar Hughes, Joseph Francis Mary Kelly, M.B., Gilbert Stewart Crawford, and John Donald Alexander, M.B.

BENGAL MEDICAL ESTABLISHMENT. — Surgeon-Lieutenant-Colonel John Burke Gaffney (dated Oct. 18th, 1891), and Surgeon-Lieutenant-Colonel Woodforde Finden (dated Nov. 2nd, 1891), to be Brigade-Surgeon-Lieutenant-Colonels.

NAVAL MEDICAL SERVICE. — The following appointment has been made at the Admiralty:—Surgeon William Spry to the *Victory* (dated Feb. 22nd, 1892).

VOLUNTEER CORPS.—*Artillery:* 1st Dorsetshire (Southern Division, Royal Artillery): Surgeon-Lieutenant J. R. Philpots resigns his commission (dated Feb. 13th, 1892).—2nd Kent: Surgeon-Captain F. Smith to be Surgeon-Major (dated Feb. 13th, 1892).—*Rifle:* 2nd (Renfrewshire) Volunteer Battalion, Princess Louise's (Argyll and Sutherland Highlanders), Surgeon-Lieutenant M. H. Taylor to be Surgeon-Captain (dated Feb. 13th, 1892).

Obituary.

PROFESSOR ALEXANDER LUMNITZER, M.D.

WE regret to have to chronicle the death of Dr. Lumnitzer, Professor of Surgery at the University of Budapest, and since 1885 a life member of the Upper House of the Hungarian Parliament. Professor Lumnitzer, the most esteemed and popular surgeon in Hungary, was born in 1821 at Kapuvár, in the county of Sofron, where his father was the superintending manager of the domains of Prince Esterhazy; his grandfather was a renowned botanist; the late Dr. Mérei, whom some may still remember as a successful physician and founder of the Children's Hospital at Manchester, was Lumnitzer's maternal uncle. After finishing his preliminary education in Pozsony and Köszeg, and devoting a good deal of attention to classical and modern languages, he pursued his professional studies at Budapest and in Vienna, and graduated at both places in 1844 and 1846 respectively. At Budapest he was assistant to Professor Balassa, and at Vienna to Professor Schuh. Lumnitzer now took the opportunity of visiting foreign universities and hospitals, particularly those of Paris, London, and Zurich. When in Paris he attended the lectures and cliniques of Velpeau, Ricord, Malgaigne, and others. During the Hungarian war in 1878–79 Dr. Lumnitzer served on the staff of General Görgey as director-in-chief of the field hospitals. After the Russian intervention and the capitulation of Világos, Dr. Lumnitzer, by way of punishment, was enrolled as a subordinate attendant on the sick at an Austrian military hospital, in which degrading position he was kept till the fall of Field-Marshal Haynau. In 1861 Lumnitzer was appointed second surgeon to the Rochus Hospital at Budapest, and in 1864 was promoted to be chief surgeon. He again found time to visit the principal schools of surgery on the Continent and in England. In 1872 he was nominated Professor Extraordinary and in 1880 Professor Ordinary of Operative Surgery at the University, which post he filled with so much credit and usefulness till his death. Distinctions began now to shower upon him. He was a member, afterwards Secretary, Vice-president, and President of the Royal Medico-Chirurgical Society of Budapest. In 1866 he obtained the Knighthood of the Iron Crown; in 1878 was made President of the National Board of Health, and appointed a Crown Councillor. In 1869 he was elected chief physician of the city of Budapest, and in 1878 he represented Hungary at the Sanitary Congress in Paris. In 1885 his sovereign conferred upon Dr. Lumnitzer the dignity of Member of the House of Magnates. Lumnitzer was an easy writer, a fluent speaker, and the author of valuable works and many professional treatises. The introduction of antiseptic surgery in Budapest owes much to him; he tried also experiments with Koch's method, and his report on that subject is his last contribution to clinical surgery. Lumnitzer was a great and skilful surgeon. The new generation of Hungarian medical men are his pupils; on them he never ceased to impress the importance of thorough work, and that without well-grounded knowledge there was no hope of future usefulness and success. In clinical instruction he called particular attention to the minutest details, and despised show and superficiality; in his strict conscientiousness he would point out his own mistakes, and discuss the difficulties which led to errors of diagnosis, and marked out the way in which they should be avoided. By his sympathetic, gentle, and genial nature, ever ready to assist with advice and otherwise, he secured for himself the universal love and esteem of his pupils and professional brethren, as well as the confidence of his patients. He died on the 30th ult., in the seventy-first year of his age, of phthisis, aggravated by a long-standing induration of part of the right lung, the result of pneumonia. He was buried beside his son-in-law, the late Dr. Géza Antal, amidst every manifestation of sincere sympathy and the sorrow of his many friends and the public.

FOOTBALL CASUALTIES. — On Saturday, in the Scottish League match, Rangers against Vale of Leven, the Vale of Leven centre forward sustained a fracture of his clavicle.—On the same day, in a match at Caversham, near Reading, a player of the Newbury Reserves sustained a compound fracture of the left leg, and was conveyed to the hospital; also, on the same day, during a game between the White Lane (Chapeltown) and Carhouse (Rotherham) Clubs, a young man met with serious internal injuries. Medical assistance was obtained, when it was found he was suffering from "rupture of the intestines," and he died the following day.—On the same day a young man, in a match between Werneth A. and Oldham Horners, was kicked in the abdomen. Medical aid was procured, but death ensued on the following day. — On the same day a youth, in a game at Tunbridge Wells between the St. John's Team and the Excelsiors, received a serious injury to the abdomen. Medical assistance was obtained, when it was found he had sustained a "severe contusion of the bowel on the right side, a laceration of the kidney; acute peritonitis following." He died on the following Friday.—On Monday, whilst playing against the Wolverhampton Wanderers, in a match at Oxford, a player fell and broke his arm.

Medical News.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.—The following gentlemen, having passed the necessary examinations, have been admitted by the two Colleges diplomates in Public Health:—

Adams, Percy Targett, M.R.C.S., Ophthalmic Hospital, Maidstone.
Bryett, Lewis T. Fraser, M.B. Lond., L.R.C.P. Lond., M.R.C.S., Girdler's-road, West Kensington.
Crosskey, Roger, L.R.C.P. Lond., M.R.C.S., Shortlands, Kent.
Daniel, W. Patrick Taylour, L.R.C.P., M.R.C.S., Robert-st., N.W.
Duthie, R. Campbell, M.B. Aberd., Stonor-road, West Kensington.
Elliot, Andrew, M.B. Edin., Edinburgh.
Greenwood, G. Spencer, L.R.C.P. Lond., M.R.C.S., Ossett, Yorkshire.
Hamerton, George Albert, M.D. Brux., L.R.C.P. Lond., M.R.C.S., Southampton-street, Strand.
Johns, John Francis, M.B. Durh., L.R.C.P. Lond., M.R.C.S., Southampton.
Macnamara, Hugh Winckworth (Surg. R.N.), L.R.C.P. Lond., M.R.C.S., Chatham.
Marsh, Thomas Alfred Perry (Surg.-Capt. Army), L.R.C.P. Lond., M.R.C.S., Aldershot.
Perry, Allan (Surg.-Capt. Army), M.R.C.S., the Guards' Hospital.
Stott, Hugh, L.R.C.P. Lond., M.R.C.S., Colney Hatch.
Tyrell, Walter Guy Beauchamp, L.R.C.P. Lond., M.R.C.S., Great Malvern.
Westcott, William Wynn, M.B. Lond., M.R.C.S., Camden-road, N.
Wood, W. Edmund, M.B. Lond., M.R.C.S., Dulwich.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen, in addition to those mentioned in our issue of the 6th inst. as having obtained the L.R.C.P., having passed the necessary examinations, and having conformed to the by-laws and regulations, were, at the ordinary meeting of the Council on the 11th inst., admitted Members of the College:—

Boyes, William Isaac, M.B. Melb., Endsleigh-gardens.
Gregerson, William Jens, M.B. Melb., Endsleigh-gardens.
Phillips, Alfred Stanbury, L.S.A., Stonehouse, Devon.

UNIVERSITY OF LONDON.—The following candidates have passed the Intermediate Examination in Medicine:—

First Division.—Harold Budgett Meakin, St. Bartholomew's Hospital; William Thomas Pugh, Middlesex Hospital.
Second Division.—Evelyn Geo. B. Adams, St. Bartholomew's Hospital; Lizzie Bennett, London School of Medicine for Women; Cecil Edward Carpmael, Guy's Hospital; Alice Mary Corthorn, London School of Medicine for Women; Percival Clennell Fenwick, St. Thomas's Hospital; John William Haines, St. Bartholomew's Hospital; Arthur Cecil Hovenden, Guy's Hospital; Gerald Stanley Hovenden, Guy's Hospital; W. David Jones, University College; Reginald Gower Kirton, London Hospital; Chas. Harris Langford, St. Bartholomew's Hospital; Antony Alexander Martin, St. Mary's Hospital; Alfred Miller, Guy's Hospital; Thomas G. Nicholson, B.Sc., St. Thomas's Hospital; Leonard Arthur Parry, Guy's Hospital; Cecil David Dale Roberts, Queen's College, Birmingham; Arthur Stanley, St. Mary's Hospital; Thomas Harold Woodfield, St. Bartholomew's Hospital.

ROYAL COLLEGE OF SURGEONS IN IRELAND: FELLOWSHIP EXAMINATION.—The following gentleman, having passed the necessary examination, has been admitted a Fellow of the College:—

William Deane, L.R.C.S.I., 1879, Surgeon-Captain, Indian Medical Service.

THE *Surrey Advertiser* publishes the following, which may have interest for athletic members of the profession. "At Guildford a few days ago, just before the commencement of the County match between Surrey and Middlesex, a boy was run over by a cart near the football field, with the result that his leg was fractured near the thigh. The Surrey player, Mr. J. J. Knox, who is a doctor by profession, was near at hand, and he skilfully set the injured limb, the unfortunate youth subsequently being conveyed on the police ambulance to the Royal Surrey County Hospital. Mr. Knox is assistant to Dr. Skimming, of East Molesey."

HUNTERIAN SOCIETY.—The following gentlemen have been elected office bearers for the ensuing session:—President: Frederick Gordon Brown. Vice-Presidents: Thos. E. Bowkett, J. Dundas Grant, M.D., C. J. Symonds, M.S., and R. G. Tatham. Treasurer: F. Charlewood Turner, M.D. Trustees: H. I. Fotherby, M.D., and F. M. Corner. Librarian: Arthur T. Davies, M.D. Orator: John S. E. Cotman, M.R.C.P. Ed. Secretaries: John Poland and R. Hingston Fox, M.D. Council: S. H. Appleford, M.D., H. W. Denton Cardew, Sir Andrew Clark, Bart., M.D., T. Rowing Fendick, J. Langton Hewer, M.D., T. Mark Hovell, Francis R. Humphreys, Stephen Mackenzie, M.D., T. Horrocks Openshaw, M.S., Reginald J. Ryle, M.B., F. J. Smith, M.D., and Henry J. Thorp.

THE CITY LYING-IN HOSPITAL, CITY-ROAD.—The annual meeting was held at the hospital last week. In the past year 455 in-patients had been treated, and 1555 out-patients received the benefits of the charity. The balance sheet showed a deficiency of £161.

ROYAL METEOROLOGICAL SOCIETY.—The usual monthly meeting of this Society was held on Wednesday evening, the 17th inst., at the Institution of Civil Engineers, 25, Great George-street, Westminster, Dr. C. Theodore Williams in the chair. The papers read included one by the Hon. Rollo Russell, M.A., on "The Untenability of Atmospheric Hypothesis of Epidemics," and another by Mr. H. Harris on "The Atmospheric Origin of Influenza Epidemics."

THE ADELAIDE CHILDREN'S HOSPITAL.—His Excellency the governor, Lord Kintore, presided at the annual meeting held on Oct. 26th last, at the institution, North Adelaide. The record of the past year's work reflected great credit upon the management. The hospital contains four general wards, two special wards, an ophthalmic ward, and a contagious ward. Accommodation is provided for forty-two patients, and usually the whole of the cots are occupied. A new building for the treatment of contagious diseases is urgently required. The facilities which the institution offers to those wishing to undertake the duties of nursing are much appreciated by the public. The cash statement showed a balance at the banker's of £1240 5*s.* 10*d.* The endowment fund now stands at a total of £2995 11*s.* 6*d.*

PRESENTATIONS.—Mr. C. M. Brady of Wigan has been the recipient of a handsome case of cutlery from his professional brethren on the occasion of his marriage. The case bore the following inscription:—"Presented to C. M. Brady, Esq., by a few of his medical friends on the occasion of his marriage, Feb. 16th, 1892."—The nurses of University College Hospital, on Feb. 11th, presented the secretary, Mr. Newton H. Nixon, with a handsomely fitted luncheon basket on the occasion of his birthday. We understand that the idea originated with the nurses whilst returning from their last summer trip to Richmond, annually organised by Mr. Nixon.—Mr. H. E. Dixon, L.R.C.P. Lond., M.R.C.S., has been presented by his friends, on his leaving Abingdon, with a valuable gold watch, bearing an appropriate inscription. At a meeting of the Society of Medical Officers of Health, held on Feb. 15th last at 20, Hanover-square, W., a handsome tea and coffee service was presented to Samuel Robert Lovett, L.R.C.P., medical officer of health for the district of St. Giles', London, by the Society of Medical Officers of Health, in acknowledgment of his many years of devoted services as treasurer of the Society.

ÆSCULAPIUS LODGE, No. 2410.—An ordinary meeting of this lodge took place at the Café Royal, Regent-street, on Wednesday, the 10th inst. A large number of members sent apologies for their absence in consequence of excess of professional work. The following officers, members, and visitors were present:—Bros. J. Brindley James, P.M., W.M., Thomas Dutton, M.D., P.M., as I.P.M. and secretary; Deputy Inspector-General Matthew Coates, M.D., R.M., P.M., as S.W.; Deputy Inspector-General Belgrave Ninnis, M.D., R.M., P.M., J.W.; Jacob Pickett, M.D., S.D.; George Crawford Thomson, M.B., J.D.; Anthony Nutt, I.G.; E. Henry Ezard, M.B., Org.; N. E. Yorke Davies. Visitors: Bros. Alfred Heald, P.M., No. 163; A. J. Phillips, No. 463; W. Molesworth St. Aubyn, No. 2369; and C. M. Simpson, M.D., No. 1056. Bros. Herbert G. Blackmore, Lewis Lewis, Montague Cheale, Frank Reid, and Clifford Luxmore Drew, M.B., made further progress in masonry, the ceremony being performed in an able manner by the W.M. Bro. Surgeon-Major William G. Black, F.R.C.S. Ed., M.R.C.S. Eng., was elected a joining member. After the routine business was concluded the brethren sat down to a capital banquet. In the after-dinner speech the W.M. alluded, in most feeling terms, to the much-lamented death of the R.W., Bro. Prince Albert Victor, Duke of Clarence and Avondale, Prov. Grand Master of Berkshire stating it was only two months ago at that festive board he alluded to the happy event of the Prince's engagement to Princess May of Teck. The sad loss masonry had also experienced by the untimely death of Bro. Colonel Shadwell Clerke, Grand Secretary, who was an hon. member of the Æsculapius Lodge, and who only last October consecrated the lodge, was also mentioned.

VIENNA HOSPITAL FOR CONSUMPTION.—Baron Albert de Rothschild has forwarded a donation of 100,000fl. to the society interested in promoting the above hospital.

ROYAL NATIONAL HOSPITAL FOR CONSUMPTION, VENTNOR.—The Queen has become an annual subscriber of £10 to the funds of the hospital, which has also been honoured by a visit from Her Majesty.

WIGAN MEDICAL SOCIETY.—The following have been elected office-bearers for 1892:—President: J. B. Stuart, Esq., J.P., F.R.C.S. Ed. Committee: C. M. Brady, ex-president, W. C. Barnish, R. Cowan, G. H. Monks, jun., J. A. Marsden, and M. Benson. Treasurer: G. H. Monks, jun. Hon. Secretary: W. Berry, F.R.C.S.I.

SOCIETY OF ARTS.—At the meeting of the Indian Section of the Society on Thursday afternoon, March 3rd, Surgeon-General Sir W. J. Moore, K.C.J.E., will read a paper on Indian Sanitation and the International Congress of Hygiene. The chair will be taken at 4.30 P.M. by Sir Owen Tudor Burne, K.C.S.I., C.I.E., a leading member of the Indian Committee of the Congress. Sir Douglas Galton and other authorities will take part in the discussion.

SUICIDE OF A LIVERPOOL MEDICAL PRACTITIONER. Shortly after twelve o'clock on Saturday last Mr. Arnold, L.R.C.P., F.R.C.S.I., of Park-road, Liverpool, was found dead in his surgery, and beside him was a vessel which had contained poison. The deceased gentleman was medical adviser to the police at the Essex-street Bridewell. He had been suffering from insomnia and depression following an attack of influenza.

LONDON FEVER HOSPITAL.—A very satisfactory report of the past year's work of this institution has just been circulated. During the year 515 patients were admitted, and, as in previous years since 1883, there was no case of typhus fever, and not a single patient admitted for one kind of fever contracted another while in the hospital. Scarlet fever had furnished the great majority of cases, and in these the mortality did not reach 1 per cent., as against 5 per cent. for the whole metropolis.

THE NEW INFIRMARY, SOUTHPORT.—The annual report for the year 1891 is just issued. There has been a considerable increase of in-patients treated during the year, and a decrease in the number of out-patients. The statement of receipts and expenditure shows a small deficit balance. An energetic effort is being made to celebrate the present year—Southport's centenary—by the erection of a new infirmary, the prospects in respect to which were very encouraging. The Scarisbrick trustees had, subject to the sanction of the Court of Chancery, promised a site of five acres in the Scarisbrick New-road, estimated to be worth £4840, while the fund for the erection of the proposed building now amounted to £7472.

BEQUESTS AND DONATIONS TO HOSPITALS.—The late Mr. Walter Davidson, of Cairnie, Fifeshire, bequeathed £1000 to the Edinburgh Royal Infirmary.—By the death of Mrs. Joseph Cole, of Pedmore, a bequest of £500, left by her late husband, becomes payable to the Stourbridge Dispensary, and Mrs. Cole also bequeathed £100 each to the same Dispensary and the Guest Hospital, Dudley.—The late Mr. John Palmer Stocker, of Oxford-terrace, Hyde-park, London, bequeathed £200 to the City of London Truss Society, £100 each to the St. Mary's Hospital, Paddington, the Hospital for Sick Children, Great Ormond-street, and the Hospital for Cancer, Brompton.—Mr. John Coppin, late of Bingfield House, Northumberland, bequeathed £500 each to the Newcastle Convalescent Society and the National Hospital for Consumption, Ventnor.—The late Mr. Charles H. Wagner, of the Hagley-road, Edgbaston, bequeathed £500 each to the General Hospital and the Queen's Hospital, £300 to the General Dispensary, £100 to the Children's Hospital, Birmingham, and £50 to the German Hospital, Dalston.—The late Mr. Samuel Maples, of Nottingham, bequeathed £1000 each to the General Hospital, Nottingham, the Nottingham General Dispensary, and the Free Hospital for Sick Children, Nottingham.

MEDICAL NOTES IN PARLIAMENT.

The Albert University.

IN the House of Commons on Monday last Mr. Roby asked the Vice-President of the Committee of Council on Education whether the Charter of the proposed teaching university had been reconsidered, and when it would be laid on the table of the House. In reply, Sir W. Hart-Dyke said that the Charter was practically settled, and would be laid on the table during the week.

Insurance of Children.

In reply to Colonel Dawnay, the First Lord of the Treasury feared that it would not be possible for the Government to introduce a measure during this session to amend and regulate the laws relating to the insurance of children.

Foot-and-Mouth Disease in Kent.

Referring to newspaper reports that this disease had spread to Kent, Mr. Chaplin confirmed the truth of the statements, and stated that from inquiries he had ascertained that the outbreak had occurred at Minster in the island of Sheppey, and an order had been issued prohibiting the removal of animals from that district, and cutting it off from other parts of the country.

Hours of Railway Servants.

In the House of Commons on Tuesday, the 16th inst., Mr. Akers-Douglas moved: "That the Select Committee be reappointed to inquire whether, and, if so, in what way, the hours worked by railway servants should be restricted by legislation; that the Committee do consist of twenty-six members; that the following be members of the Committee—Sir Michael Hicks-Beach, Mr. Channing, Mr. Radcliffe Cooke, Mr. Crawford, Baron de Worms, Mr. Alfred Gathorne-Hardy, Mr. Herbert Gladstone, Mr. Heneage, Mr. Howorth, Mr. M'Innes, Mr. MacNeill, Mr. Walter M'Laren, Mr. Maguire, Sir Herbert Maxwell, Mr. Milvain, Mr. Muntz, Mr. Murdoch, Sir Joseph Pease, Mr. Pickard, Sir Edward Reed, Sir Albert Rollit, Mr. Somervell, Sir George Trevelyan, Sir Henry Tyler, Mr. Vernon, and Mr. Johns Wilson; that the Committee have power to send for persons, papers, and records; that five be the quorum." The motion was agreed to.

The International Sanitary Conference at Venice.

In the House of Commons, on Thursday, Dr. Farquharson asked the Under Secretary of State for Foreign Affairs whether the draft of the protocol submitted on behalf of England to the International Sanitary Conference at Venice, which had to be withdrawn in favour of propositions submitted by the French delegates, was drawn with the assent and aid of the Medical Department of the Local Government Board, or of any other competent official medical advisers of the Government.—Mr. J. W. Lowther replied that the protocol referred to did not contain any new medical regulations or proposals on questions of hygiene, and it was not therefore necessary to consult the medical advisers of the Local Government Board upon it. The protocol was not withdrawn as stated in the question. The proposals submitted by the French delegates were submitted as amendments to the protocol. All the departments of Her Majesty's Government interested were consulted in the preparation of the instructions to the British delegates.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward it to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week for publication in the next number.*

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editors."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

We cannot undertake to return MSS. not used.

RELIEF OF THE ITCHING OF MEASLES &c.

AN ointment composed of lanoline 50 parts, vaseline 20 parts, and distilled water 25 parts has been found by Dr. Klein to be a most soothing application for the relief of the itching accompanying the rashes of measles, scarlatina, and chicken-pox.

Bethnal Green.—Facts are to be carefully noted. If they show clearly that a practitioner covers an unqualified person who does all the medical attendance, and that the said practitioner signs certificates of death in cases which he has not personally attended, they should be transmitted to the General Medical Council and to the Registrar-General with a request for attention to them.

Dr. Craigie.—We have already referred incidentally to the point raised by our correspondent; but probably, as the epidemic is rapidly subsiding, there would be no advantage now in further discussing the question.

Mr. Charles Slater.—Yes.

THE MEDICAL PROFESSION AND THE LAY PRESS.

DR. MACNAUGHTON JONES has sent us the letters of the editor of a London evening contemporary, referring to an article on astigmatism which appeared in that paper, in which Dr. Jones's name and sentences from a work of his were quoted, ostensibly to impress the importance of the subject of astigmatism on the public. The greater part of the article, however, was taken up with the praises of a certain optician's glasses. In this correspondence regret is expressed that anything should have been inserted calculated to annoy or injure any professional man, and an explanation is given of the way in which the article came to be written.

Tyro.—In the By-Laws and Regulations of the Royal College of Physicians occurs the following:—"On the 10th day of April, 1878, the College passed the following resolution: 'No Fellow, Member, Extra-Licentiate, or Licentiate of the College shall be authorised or entitled by virtue of any Diploma or Licence granted by the College to assume the title of Doctor, or to append to his name the title of Doctor of Medicine, or the letters M.D., or any other letters indicating that he is a Graduate in Medicine of a University.'"

Medicus (Liverpool).—The answer must be in the negative, at all events until further light is thrown upon the subject.

Delta.—The question is still an open one, and seems likely to remain so for some time to come.

G. P. is referred to the reply given to another correspondent, who propounds a similar query.

Mr. Donaldson (Londonderry).—Yes, in an early number.

INJUSTICE UNDER THE NOTIFICATION ACT.

To the Editors of THE LANCET.

SIRS,—May I ask you kindly to give me advice on the following? Under the Notification Act I sent in a certificate to the medical officer of health to say a certain R. H—— was suffering from erysipelas. The 2s. 6d. is disallowed in my quarterly bill, and on calling on the borough accountant I find that against the entry is written, "R. H—— said he had not erysipelas." This, the accountant says, was written by the medical officer, and is signed by him. On calling on the medical officer, he informs me that the man R. H—— stated that he did not have erysipelas, and that was his reason for withholding the 2s. 6d. fee. R. H—— has since died, and I have seen his wife, who has signed a paper to state that I did attend her late husband for erysipelas. The reason I am writing this is that if the patient's word is to outweigh ours, what is the good of the Notification Act?

I am, Sirs, faithfully yours,

February, 1892. J. W.

*** We refrain from comment on the above case until time is given for a reply by the medical officer of health. If the statement of the patient is to supersede and neutralise the notification of the medical man, and the medical officer of health is to be the active agent in such a result, the notifier may well ask, What is the use of the Act? We wait for a reply.—ED. L.

C. P. M. S.—1. Unless an agreement exists with a principal by which the assistant is to receive fees for special services, such as those mentioned, the principal is entitled to whatever is earned in the practice.—2. The coroner must pay £1 1s. for evidence, if given in a professional capacity.—3. It is usual for magistrates to allow 10s. 6d. for each day's attendance at the police-court.—4. Our correspondent is entitled to £1 1s. for each day's attendance at assize. Sundays do not count. It is customary to allow second-class travelling expenses, but not hotel expenses.

Perplexed.—Such coöperation with an obvious quack is decidedly unprofessional conduct. It is not very different from that of a practitioner who is associated with an unqualified assistant not under his immediate supervision. It should be protested against by the whole profession of the town, and the protest should be forwarded, with proofs, to the licensing body whose diploma is held by the practitioner, and to the Medical Council.

Mr. J. L. Firth (Bradford).—The paper has been received, and will appear very shortly.

Dr. Hedley (Brighton).—The paper is marked for insertion.

TREATMENT OF ECLAMPSIA.

To the Editors of THE LANCET.

SIRS,—Having noticed in THE LANCET of Jan. 2nd, 1892, Dr. Leopold Roheim's treatment of eclampsia by compression of the common carotid, I beg to state that during the last four years I have often successfully practised this method, having obtained the idea when reading Solly on the Human Brain, where, in his article on "Epilepsy," he recommends ligature or compression for the fits.

I am, Sirs, yours truly,

J. B. SPEARING, L.R.C.S.I., L.A.H.

Broughton-in-Furness, Feb. 13th, 1892.

INFLUENZA.

DR. R. SISLEY, controverting the air-borne theory spoken of by Dr. Fitzgerald in THE LANCET of Nov. 7th, 1891, says he believes that teaching to be entirely erroneous. He has not seen any evidence in this epidemic and in this country that disease has anywhere occurred under circumstances which exclude the possibility of infection having been contracted from human sources. The rate of spread of influenza has a direct relation to the rate of human transit in a country. In Europe it was rapid; in India it was slow. In proof of this he quotes the report of Surgeon Roberts, of the Indian Medical Service, which gives a description of the attack which occurred in the valleys of the Hindu Kush during last autumn, and which appeared at Gilgit in December, 1890. This report states that "the evidence in favour of its having spread by human intercourse along the lines of road communication, and not disseminated by the atmosphere, is so great indeed that in this instance it seems impossible to find any support for the latter theory."

MR. JAMES PARKER writes that he has used a pill of quinine, iron, and zinc valerianate for prostration in cases of influenza with markedly good results. He thinks the prepraation is worthy of a more extended trial.

DR. E. FURNISS POTTER is of opinion that phenacetin is a most valuable drug to use in influenza as an antipyretic, hypnotic, and anodyne. He also notes a resemblance between the temperature of influenza and that of enteric fever.

DR. MOWBRAY TAYLOR has had successful results in treating influenza with a salt of picric acid—the picrate of ammonium. As the basis of his treatment he administers a saturated solution of this salt in from five to ten-minim doses, every four hours, with ten minims of the liquor morphiæ in a little chloroform water. Being a derivative of carbolic acid, he thinks it owes its success to its chemical properties as a germicide when absorbed into the system.

MR. W. J. BLACK points out that the contagious nature of influenza is referred to in Cullen's Synopsis, January, 1785, page 174, under the heading "Catarrhus e Contagio." Hooper's Medical Dictionary, 1820, states the same. Our correspondent refers also to the Cyclopædia of Medicine, 1833. The Army Medical Reports, 1859, places the disease amongst the miasmatic and zymotic diseases. Mr. Black also points out glaring instances of disregard of this old experience.

"POISON BOTTLE-STAND."

To the Editors of THE LANCET.

SIRS,—When reading in the current issue of THE LANCET an account of Mr. Mennell's bottle-stand, by which the inadvertent use of poisonous drugs may be avoided, a very ingenious electrical contrivance which I saw about two years ago in the establishment of a chemist at a well-known seaside resort was recalled to my mind, a description of which may probably be of interest to some of your readers. Under each bottle containing a poisonous substance, as it stood on its shelf, was placed a small metallic disc, which was connected by a wire with a battery. When a bottle was removed a bell was immediately rung, and continued to ring until it (the bottle) was replaced, thus giving unmistakable evidence of the fact that a poisonous drug had been touched. In a word, the action was that of an ordinary electric bell *reversed*—i.e., the bell rang when pressure on the disc (caused by the weight of the bottle) was removed, and *vice versâ*. I may mention that Mr. —— assured me at the time that the apparatus worked well, was most simple of construction, and very inexpensive. Individually, I must confess I do not see why there should be any necessity for such appliances, as, if one will only exercise ordinary care in dispensing medicines, we should not read of so many lamentable accidents in the daily papers.—I am, Sirs, yours faithfully,

H. CLINTON DAVIES, L.R.C.S., L.R.C.P. ED., &c.

Hackney, Feb. 13th, 1892.

MEDICAL CHARGES IN SOUTH AFRICA.

THE *Port Elizabeth Telegraph* has a very sensible article on a discussion in the Afrikander Bond on unreasonable medical charges in country places. The *Telegraph* is properly sceptical of the truth of such charges. The rough and long journeys to be made and the hard professional duties to be done make good charges a binding duty on the medical adviser. The value of his life and time must be considered.

Dr. W. Arthur Bullen.—A medical man notifying cases of scarlet fever is not required to specify rash or any other symptom. The Act mentions no points or particulars of diagnosis, but provides only that every medical practitioner "on becoming aware" that a patient is suffering from an infectious disease to which the Act applies "shall send to the medical officer of health a certificate stating the name of the patient, the situation of the building, and the infectious disease from which, in the opinion of such practitioner, the patient is suffering."

Mr. W. R. Goodfellow.—The decision of the magistrates was not inconsistent with physiological laws.

ABSTRACT OF

Contributions

TO THE

PHYSIOLOGY AND PATHOLOGY OF THE MAMMALIAN HEART.[1]

(From the Cambridge Pathological Laboratory.)

BY C. S. ROY, F.R.S., M.D.,
PROFESSOR OF PATHOLOGY,
AND
J. G. ADAMI, M.A., M.B.,
FELLOW OF JESUS COLLEGE, CAMBRIDGE.

IN studying the action of the mammalian heart we have sought to examine the organ under conditions, unexcised and intact, as nearly approaching the normal as are compatible with the employment of exact methods of research—in short, to make our observations approach in exactitude those which have been made upon the hearts of cold-blooded animals. And we have found two instruments of especial use—one, which we term the "cardiometer," a form of cardiac plethysmograph or oncograph, which records the changes in volume of the whole heart; the other a myocardiograph, whereby we could record the contractions or expansions of any part or parts of the auricular or ventricular walls without interfering with the movements of the heart as a whole. In most cases we employed this instrument to obtain simultaneous records of the contraction of one auricle and one ventricle. These instruments are fully described in our complete paper which will shortly be published.

In order to interpret the results gained by any form of recording apparatus applied to the mammalian heart it is necessary to keep in mind continually certain elements of the mechanics of the subject, for neglect to do this has led to much confusion and erroneous statement. Thus the ventricles may be looked upon as roughly spherical, and it is most important to remember the relationship between the circumference and the cubic contents of a (elastic) sphere, according to variations in the diameter or circumference of that sphere. When such a sphere is enlarged a very slight diminution in its circumference is capable of throwing out a quantity of the contained fluid, whose expulsion in a sphere of smaller diameter would be associated with a very considerable diminution of circumference. For example, reduction by one inch in the circumference of a sphere of five inches in circumference is accompanied by a reduction of the contents equal in amount to that which accompanies the lessening by a quarter of an inch of the circumference of a sphere of ten inches in circumference, although in the one sphere the circumference is lowered one-fifth, in the other one-fortieth. It is important also to keep in mind that the strain on the walls of a hollow spherical shell increases uniformly with the circumference—in other words, that the resistance to contraction of the ventricular walls becomes greater as the circumference is increased. It is well also to note that a change of pressure in the aorta or pulmonary artery has the same effect on the resistance to contraction offered to the left or right ventricular walls as obtains in the case of a parallel-fibred voluntary muscle by increasing or lessening the weight against which it is made to contract by single induction shocks, causing maximal contractions. If the weight be increased, although the same amount of work be done, the extent of shortening in contraction is diminished, and *vice versâ*. An analogous result takes place in the case of the ventricles. When from any cause the resistance to contraction is increased, or the force of contraction is reduced, their walls contract less completely, so that there is an increase in the amount of "residual blood" left in the cavities at the end of systole. The presence of such residual blood can be determined by the cardiometer, and, indeed, by the naked eye, in a variety of conditions, among which, as we proceed to show, vagus excitation is to be included.

Studying the action of the vagus upon the heart, we find that excitation of this nerve slows and weakens or stops the auricular contractions, and this weakening or arrest is a potent factor in bringing about the increased systemic and pulmonary venous pressure and in modifying the action of the ventricles. Up to a certain point the ventricles tend to follow the "sinus" rhythm, and to this extent vagus slowing of the auricles induces ventricular slowing. But when the vagus excitation reaches a certain degree (varying in different animals), the ventricles begin to beat independently of the sinus and auricles; and this rhythm, which is at first slow and irregular, gradually becomes fairly rapid and almost completely regular. This rhythm, we show, must be looked upon as the same as that which, as Wooldridge and Tigerstedt observed, makes its appearance when the ventricles are severed from the auricles. We point out, however, that the independent ventricular rhythm of vagus action is characterised by the slowness with which it establishes itself. This characteristic is due to the lowering of the excitability of the ventricles produced by vagus action, and we adduce a considerable number of facts showing that the vagus *does* lower the excitability of the ventricles, and that, by means of muscarin and by discontinuous stimulation of the vagus, it is possible to isolate the influence of the vagus on the rhythm and force of the auricles from its influence upon the excitability of the ventricles. The power of the vagus to stop the ventricles temporarily can only be explained by this diminution of their excitability. We show that, with a certain degree of vagus excitation, irregularity of the ventricles necessarily results, in consequence of the sinus and the idio-ventricular rhythms interfering with one another; that this is the common cause of irregularity; and that irregularity may also be caused by the auricles not responding to all the impulses which reach them from the sinus.

In consequence of this slowing of the rhythm and lessened excitability of the ventricular walls, the ventricles become distended in diastole, this distension being also aided by the fact that the increased venous pressure must lead to a greater amount of blood being poured into the cavities between the beats. And this dilatation of the ventricles is not simply diastolic, but is also systolic—the ventricular cavities are relatively distended at the completion of systole. It must not, however, be thought that this increase in the residual blood indicates a lessened force of contraction of the ventricular muscle due to the action of the vagus. Of such weakening of the ventricular muscle we find no proof. A consideration of the principles enunciated at the beginning shows that residual blood is not a necessary indication of lessened force of contraction, and that, if the ventricles be dilated, a comparatively slight extent of contraction leads to the expulsion of a comparatively large quantity of blood. And, as a matter of fact, we find that, while through the slowing of rhythm which accompanies vagus excitation, the output of the heart—that is to say, the amount of blood expelled in a given time—undergoes considerable diminution, the "contraction volume" or amount of blood thrown out at each individual beat is not lessened, but, on the contrary, greatly increased. The diminution of arterial pressure does not suffice to explain this increase. We therefore conclude that, as stated above, the vagus does not lessen the force of contraction of the ventricles.

Studying the effect of direct excitation of the nervi augmentores (accelerantes) upon the heart, we show that the acceleration of the rhythm may be extremely slight if the heart be beating fast, and that the acceleration and augmentation of force of the heart bear no constant proportion to one another. The augmentor nerves increase the diastolic expansion of the auricles and also increase their systolic contraction; but these two effects do not go hand in hand. Excitation of the augmentors increases the output of the heart, owing to the increased force and frequence of the auricular contractions, the result of this being that the pressures in the systemic and pulmonary arteries rise, while the systemic and pulmonary venous pressures fall. If there be but little quickening, the contraction volume of the ventricles is increased. The augmentors, on direct stimulation, cause a slight increase in the diastolic expansion of the ventricles, which is passive

[1] Communicated to the Royal Society on Feb. 11th, and printed by the kind permission of the President and Council.

Digitized by Google

in nature and due to the increased force of the auricular contraction. The force of the ventricular contractions is increased; they contract more completely, diminishing the amount of residual blood, in spite of the fact that the arterial pressure is usually somewhat raised. Reflex excitation of the vagus produces results which are the same as those of direct excitation of the nerve, and the curves are more typical and satisfactory than those obtained on direct excitation. Excitation of a mixed nerve like the sciatic usually produces effects on the heart similar in kind to those due to direct excitation of the augmentors, but the phenomena are complicated by the greater rise of the pressure in the systemic arteries. Sometimes the increase in force of the ventricle more than counterbalances this increased resistance to contraction, and the amount of residual blood in the left ventricle is reduced; in other cases the increase in force of the ventricular contractions is not sufficient to counterbalance the increased resistance, and the residual blood in the left ventricle is increased.

We show that excitation of the central end of a mixed nerve like the sciatic or splanchnic usually affects both the augmentor and vagus centres in the medulla, and that, in nearly all cases, the augmentor centre is the more strongly excited of the two, so that augmentor effects show themselves during the excitation, but are succeeded by vagus action on ceasing to excite the nerve. In many cases augmentor effects alone show themselves. When excited reflexly the augmentor centre ceases to act earlier than the vagus; the opposite, therefore, to what takes place with direct excitation. In rare cases the excitation of the vagus centre may be stronger than that of the augmentor from the first. Although, in the absence of any augmentor action, the vagus does not reduce the force of the ventricular systole, it does unmistakably have the power of inhibiting the strengthening influence which the augmentors exert upon the ventricular contractions. As to the part played by the vagus in the economy, we show that vagus excitation relieves the heart of work, and therefore of waste, to as great an extent as is compatible with a continuation of the circulation, and conclude that the vagus acts as a protective nerve to the heart, reducing the work thrown upon that organ when from fatigue or other cause such relief is required by it. The presence of fibres in the sciatic and other mixed nerves which cause reflex excitation of the vagus would seem to indicate that this nerve may be used by other parts of the body to diminish the output of the heart and lower the blood-pressure, thereby reducing the activity of the circulation as a whole. The influence of the blood-pressure in the systemic arteries on the degree of vagus activity and the readiness with which the vagus centre is called into play by raising the intercranial pressure indicate that the vagus mechanism is specially employed in lowering the circulation so as to limit cerebral congestion. The vagus acts chiefly in the interests of the heart and central nervous system. The power of the vagus over the heart is limited, and the idio-ventricular mechanism which comes into play when the vagus action exceeds a certain limit must be looked upon as the means by which arrest of the circulation and death is prevented, whenever from any cause the nerve exerts a maximum influence. The power of the vagus to lower the excitability of the ventricles makes their temporary arrest possible; but this reduction of the excitability of the ventricles cannot be kept up, no matter how strong the stimuli applied to the nerve, for a period long enough to endanger the economy.

The function of the augmentor in the economy is to increase the work and tissue waste of the heart as part of the mechanism by which the nervous system governs the circulation, and the augmentor mechanism sacrifices the heart in order to increase the output of the organ and enable the ventricles to pump out their contents against a heightened arterial pressure. Such excessive action of the heart is limited by the vagus, which, as we have seen, readily steps in so soon as the call for an increased supply of blood has ceased. It may do so earlier, presumably because the increased blood-pressure or the fatigue of the heart calls for vagus intervention.

Considering the mode of interaction of the vagi and augmentores, we point out that when the vagi are paralysed by section or atropine, the augmentores have no control over the cardiac rhythm, and that therefore they can only act by inhibiting the influence of the vagi on the rhythmic centre of the heart. When neither nerve is acting on the auricles they contract with a certain force, which is increased by the augmentores and diminished or inhibited by the vagi. The force of the ventricular contractions is increased by augmentor action; this increase can be inhibited by vagus excitation, which latter has otherwise no power to reduce the strength of ventricular contractions. The force of the heart's contractions is influenced by other factors than the vagi, augmentores, and other nerves. The pressure of the blood in the coronary arteries is one of the most important of these factors. If this be lowered, the contractions of both auricles and of ventricles diminish in strength, while a rise of pressure in the systemic arteries causes an increase in the force of the heart's contractions, so that the force of the heart's contractions is to a certain extent regulated automatically by changes in the blood-pressure in the aorta, which is one of the variable quantities affecting the work of the left ventricle. Change in the volume of blood in the body affects greatly the contraction volume and output of the heart. Injections into the veins of a volume of defibrinated blood equal to one-tenth of the total blood in the body may double the output. It is important to note here that there is no increase in the strength of the ventricular contractions; increase in the work, therefore, of the ventricles due to increase in the output has no tendency to automatically increase the force of the ventricular contractions, as is the case with rise of pressure in the systemic arteries. We refer to the bearing of this in cases of plethora. Increase of the watery constituents of the blood increases the contraction volume and output to the same extent (though only temporarily) as does transfusion of blood, but acts more unfavourably on the heart, seeing that the work done by the ventricles is increased, while the nutritive value of the blood supplied to the coronaries is diminished. The increased output of the heart both in plethora and in hydræmia is due to rise of pressure in the systemic veins, increasing the volume of blood which enters the right ventricle during diastole. We refer to the bearing of these facts upon the treatment of chlorosis and heart disease.

In strictly physiological conditions, and in spite of the beautiful mechanism by which the force of the ventricular contraction is regulated, the heart, like the voluntary muscles of the body, is liable to fatigue when the work thrown upon it greatly exceeds that required to maintain the circulation under ordinary circumstances. We take as example the increased work thrown upon the organ during active muscular exertion, and show that exertion and endurance of fatigue are limited mainly by the limited power of the heart to continue supplying the increased amount of blood which is required by the acting voluntary muscles. We show that those luxuries which are forbidden or limited in "training," and which are known to hinder prolonged exertion, such as water, alcohol, tobacco, caffein, all directly weaken the force of the heart's contractions, and, in the case of water, place the organ under a disadvantage; also that fatigue of the heart leads to dilatation of the organ. On comparing the power of fatigued ventricles to carry on increased work, as compared with well-nourished, unfatigued ventricles, it is found that not only is the strengthening effect of the augmentor nerves upon the individual contractions less in the former case, but also that the fatigued, and therefore dilated, heart is *per se* unfavourably placed for meeting increase in the work thrown upon it. An explanation is given of the reason why in heart disease failure takes place during exertion. The part played by the vagus in protecting the diseased heart from harmful overwork is referred to, and it is shown that irregularity of the heart in disease may be explained by the mode in which this nerve, when acting powerfully, releases the ventricles from the control of the rhythmic centre in the sinus. The chief forms of rhythmic and arhythmic irregularity are considered, and it is shown that these correspond with the forms of irregularity which can be produced by vagus action. The irregular heart expends more energy, and its tissues therefore are more wasted, for a given amount of work than the heart which is beating regularly. The effect upon the heart of imperfect aeration of the blood is, first of all, to produce powerful vagus action from the medullary centre; this is usually, though not always, accompanied in curarised animals by diminution of the output of the heart. But reasons are given for assuming that the output would be increased in uncurarised animals, owing to the high venous pressure which results from

Digitized by Google

struggling. Besides the vagus action, it can be shown that asphyxia causes progressive weakening both of the auricles and of the ventricles, and attention is drawn to the fact that the considerable rise of pressure in the systemic arteries in asphyxia is accompanied by vagus effects upon the heart, and not by augmentor action, as is the case, so far as we know, in all other instances in which the vaso-constrictor centre is excited in the normal individual. It is noted that the change in the heart and circulation which takes place during asphyxia points to the conclusion that, when the total amount of oxygen in the blood is lowered, it is for the benefit of the economy that those organs, such as the central nervous system, whose continuous blood-supply is a vital necessity, should be richly furnished with blood by constriction of the vessels of the spleen, kidney, and digestive system, whose blood-supply can be cut off temporarily without danger to life, and also that the heart should carry on the circulation in a manner involving as little as possible waste of its own substance. This, as we have seen, it is the function of the vagus nerve to bring about.

Lecture

ON

TISSUE- OR CELL-FIBRINOGEN IN ITS RELATION TO THE PATHOLOGY OF BLOOD.

Delivered at the Theatre of the Laboratories of the Conjoint Colleges of Surgeons and Physicians, on Feb. 4th, 1892,

BY A. E. WRIGHT, M.D. DUB.,

LATE GROCERS' RESEARCH SCHOLAR.

THE first step in the direction of the acquirement of a control over the processes of coagulation in the living body was made by Wooldridge when he succeeded in demonstrating that intra-vascular coagulation could be obtained by the injection of solutions of tissue-fibrinogen. I do not think that I am over-estimating the importance of this discovery; for when it had been confessed by Schmidt's own pupils[1] that the injection of practically unlimited quantities of fibrin ferment into the vessels made the blood more liquid instead of producing coagulation in it, it became evident that there was no possibility of influencing the coagulability of the blood by following the lines of the fibrin-ferment theory. Now Wooldridge's work was a departure on new lines, and he succeeded in the most brilliant manner in demonstrating that it was possible by working upon these new lines to obtain a practical control over the phenomena of coagulation in the living body. It is to the facts that Wooldridge discovered, and to such others as I have been able to add to them or to bring into relation with them, that I would wish to direct your attention this afternoon. And to begin with, I would like to say that in ascribing the credit of the method of producing intra-vascular coagulation to Wooldridge I believe that I am only giving him what is strictly his due; for, although Groth,[2] one of Schmidt's pupils, had described the occurrence of intra-vascular coagulation in connexion with the injection of leucocytes in 1884—i.e., before the date of Wooldridge's publication—he had elicited the phenomena in a much less distinct manner, and he had not determined to what constituent of the leucocyte the intra-vascular coagulations were due. Instead of this he ascribed these coagulations to a production of fibrin ferment in the blood—that is to say, Groth ascribed his coagulation to a cause which we know to be quite ineffective. I think we need not therefore consider a question of priority here; but, on the other hand, we shall do well to keep in view the fact that Groth was successful in obtaining intra-vascular coagulations by the injection of the expressed juice of lymph-glands, and we have to note also that Groth regarded his experiments as conclusive as to the participation of leucocytes in the processes of coagulation. Groth's work thus opens up a number of important issues, which we shall have to consider in connexion with the production of intra-vascular coagulation by tissue-fibrinogen.

First, with regard to the relation of white corpuscles to coagulation, we are met by the fact that Wooldridge not only did not consider that Groth's experiments proved the existence of any such relation, but he went further than this, and expressed it as his opinion that the leucocytes of the blood had not been shown to stand in any relation whatever to coagulation. Wooldridge based this view, for the one part, on certain defects in conclusiveness in the evidence which had been adduced by Schmidt and his pupils to implicate the leucocytes in the processes of coagulation. Schmidt had, for instance, described the superior coagulability of the so-called granular layer which is seen above the corpuscular layer in horse blood which has been kept from coagulation by cooling; and Schmidt had asserted the granules of that layer to be with certainty derivatives of disintegration of white blood-corpuscles, and upon this assumption he had concluded that the superior coagulability of the granular layer was evidence of the participation of the leucocytes in coagulation. Wooldridge, however, pointed out that there was a flaw in this evidence, inasmuch as Schmidt had not excluded the possibility of these granules being derivatives of the plasma—i.e., the possibility of their being simply a precipitate produced in the plasma by cooling. In this connexion Wooldridge showed that peptone plasma gives such a precipitate on cooling, and I may say that I have observed that a similar precipitate can invariably be produced by the action of cold upon decalcified plasma. It follows, I think, that the argument from the superior coagulability of the granular layer must be finally abandoned. Again, with respect to the experiments of Groth and afterwards of Krüger,[3] in which an increased coagulability was observed after leucocyte injections, Wooldridge drew attention to the fact that the experiments were conducted with insufficiently isolated leucocytes, and pointed out that a fallacy was, in his opinion, introduced into them by the fact that the lymph plasma which was injected along with the lymph cells contained a coagulative substance—namely, tissue fibrinogen. Further, Wooldridge repeated the experiments of Groth and Krüger with washed leucocytes, and found that he obtained a diminution instead of an increase of coagulability in the blood. These appear at first sight to be very grave, if not fatal, objections to Schmidt's view of the important *rôle* of the white corpuscles in coagulation; still I hope to be able to show that it is possible to settle satisfactorily with them.

First, with regard to the defective isolation of the cells which was insisted upon by Wooldridge, it must be conceded that Groth's leucocytes were not at all isolated. They were simply injected along with the inter-cellular fluid of the lymph gland. With regard, further, to Krüger's attempt at isolation by means of filtering off the lymph plasma, Wooldridge is probably also correct in stating that this method is entirely ineffective, inasmuch as any attempt to filter off leucocytes from a solution of tissue fibrinogen would be rendered futile by the fact that a considerable amount of tissue fibrinogen would invariably be retained on the filter. It is evident, therefore, that we have to concede to Wooldridge that neither Groth's nor Krüger's experiments were performed with isolated leucocytes.

When we come to the second heading of the objection, which is based upon the fact that the lymph plasma contains tissue fibrinogen, and would thus introduce a fallacy if not effectually separated from the leucocytes before injection, we must, however, pause for consideration. It is not at all necessary to meet this objection by asserting that there is no tissue fibrinogen in the lymph plasma. Wooldridge was a very careful observer, and we may well accept the fact upon his statement; but we may, on the other hand, with advantage inquire how the tissue fibrinogen got into the lymph plasma; and when this question is once formulated, it is easy to see that the answer must be that the tissue-fibrinogen is almost certainly derived from the disintegration of leucocytes, inasmuch as Wooldridge himself has shown that the lymph cells contain this substance. We thus see that if the coagulative substance of the lymph plasma was derived from the leucocytes, the contamination of the leucocytes with this plasma

[1] Jabowicki, Birk, Köbler: Disserts., Dorpat, 1875, 1877, 1880. Edelberg's contradictory results (Archiv f. Exp. Path., 1880) may be neglected. They were obtained with extraordinarily impure fibrin-ferment solutions.

in the experiments of Groth and Krüger cannot be considered to vitiate their results with reference to the connexion between leucocytes and coagulation. Lastly, as to Wooldridge's objection that the injection of washed leucocytes from lymphatic glands produces increased fluidity instead of increased coagulability of the blood, it will be evident among other things that the extraction of the contained tissue-fibrinogen in the processes of washing would easily account for this result, the injection of washed leucocytes being in point of fact equivalent to an injection of attenuated leucocytes.

Having thus cleared our way from the obstacles which seemed at first to forbid us to contemplate the possibility of there being an essential unity in the results obtained by Wooldridge with tissue-fibrinogen injections and the results obtained by Groth and Krüger by their injections of leucocytes, we may proceed to inquire whether there are any positive grounds for assuming the fundamental identity of the phenomena. And here we have, first of all, to note the fact that tissue-fibrinogen—or, as I might perhaps venture to call it, "cell-fibrinogen,"[4]—though found also in the cells of the testicle, and I believe also of yeast—is yet pre-eminently a constituent of the leucocytes of the thymus and of the lymphatic system generally, and we must regard these leucocytes as at least potential blood leucocytes. Here, then, we have immediately an important link between leucocytes and tissue fibrinogen. With reference to this, however, we again find that Wooldridge was not satisfied of the conclusiveness of the argument. There might well be, argued Wooldridge, all the difference in the world between the leucocyte of the lymphatic system and the leucocyte of the blood; and further than this there was, in his opinion, distinct reason to believe that the lymph cell puts off its old nature and assumes an altogether new one when it once obtains access to the blood stream. This was Wooldridge's view; and here again, since I wish to push my argument beyond the leucocyte of the lymph to the leucocyte of the blood, I am compelled to dwell a little on the question as to whether a lymph cell is in any way demonstrably different in its chemical character from a blood leucocyte. If I understand Wooldridge aright, the experiment he relied upon as establishing a difference between the leucocyte in the gland and the leucocyte in the blood was the following. He took lymph cells and added them to "strong peptone plasma," which is not coagulable by the addition of leucocytes. He then collected his leucocytes again from this strong peptone plasma and proceeded to add them to a weak peptone plasma, which is invariably coagulable by the addition of leucocytes. The leucocytes which he now added, however, failed to coagulate it, and the conclusion which was drawn by him from this fact was that the leucocytes had undergone some fundamental alteration in their chemical constitution during the period of their stay in the strong peptone plasma. Such a change of nature Wooldridge considered to be associated with the passage of the lymph cell over the threshold of the blood. The experiment in question is, however, hardly sufficient to establish this, and it is not at all difficult to put a different construction upon it than that which Wooldridge attributed to it. I think we are, in fact, constrained to do so in view of the facts which have been elicited by Rauschenbach in connexion with the chemical and physiological properties of the leucocytes. The researches in question I believe conclusively establish that though there is an undoubted line of distinction which can be drawn between leucocyte and leucocyte, that line cannot be drawn so as to include all the white blood-corpuscles in one category and all the lymph cells in another. Rather the distinctions can be more naturally explained with reference to differences in maturation in the leucocytes whether these occur in the blood stream or without it. The physiological differences between leucocytes are apparently only quantitative differences, but they are at least very appreciable quantitative differences, and they permit of our sorting the leucocytes into two classes. The basis of this classification would be the greater or less stability of the leucocyte as shown by its resistance to disintegration when it is introduced into a spontaneously coagulable plasma. It is, however, to be noted that such a coagulable plasma has the power of disintegrating any leucocyte[5] whatever which is added to it, and of using up one of its constituents, not, it must be noted, its paraglobulin, but its tissue- or cell-fibrinogen in the formation of fibrin. When, however, it comes to be a matter of choice, the plasma naturally employs for its purposes the more easily disintegrated leucocytes which have been described by Rauschenbach as the α-leucocytes. These α leucocytes are distinguished from the β leucocytes, also by certain more strictly chemical characters. They, for instance, stain in carmine only with extreme difficulty, whereas the β-leucocytes take on the stain almost instantaneously. Again, the α leucocytes further show their defect in stability by undergoing a slimy metamorphosis when they are treated either with NaCl solutions of moderate strengths, or with dilute caustic alkalies. These characters are, I think, possibly due to the presence of considerable quantities of tissue-fibrinogen in the α-leucocyte.

When these differences between leucocytes had been established Rauschenbach proceeded to the study of what we may call the geographical distribution of the α- and β leucocytes, but it is only possible to glance at the main results of his most interesting work so far as they affect the questions at present more directly under discussion. It is, for instance, of direct importance to us to note that both α- and β leucocytes are found to be present in the lymph glands, and, further, that the same two varieties of leucocytes are found also in the blood. We thus see that Rauschenbach's observations do not support the theory of the essential duality of the blood leucocytes and the lymph leucocytes. Rauschenbach's work further indicates the lines upon which the explanation of Wooldridge's experiment is to be sought, for we can now see how it is almost certain that Wooldridge must have added to his "strong peptone plasma" a mixture of α- and β leucocytes, and it is probable that he would, under the circumstances, only have recovered the less easily disintegrated β-leucocytes from it—i.e., leucocytes whose coagulative power may have been inadequate to bring about coagulation in his weak peptone plasma. The result obtained would then easily be accounted for without the hypothesis of the leucocyte putting on a new nature when it entered the blood. Similarly we could on these lines account for Wooldridge's observation that the inter-cellular fluid of the lymph glands was much more potent in inaugurating coagulation than the isolated lymph cells. The α-leucocytes, which disintegrate easily, would naturally pass into solution in the lymph plasma and impart their coagulative efficacy to it, while the more resistant cells, which survive the chemical processes involved in isolation, probably consist of β leucocytes in which the coagulative power is at its minimum. This may in part account for the relative coagulative inefficacy of the leucocytes employed by Wooldridge in his injection experiments. We shall, however, have to return to this subject at a later stage of this lecture.

We have in this manner, if my arguments are correct, disposed of the objections which Wooldridge raised to admitting the coagulative influence of leucocytes, and we have now only to establish that the phenomena observed after the injection of tissue-fibrinogen are identical with the phenomena seen after the injection of leucocytes, before we proceed to vindicate that wider importance for tissue-fibrinogen coagulations which would naturally accrue to them if they were shown to stand in relation to any increased disintegration of leucocytes in the blood.

I shall therefore proceed to describe to you from Wooldridge's work on the subject and from work of my own, which was directed to follow up Wooldridge's researches, the phenomena observed after the injection into the blood of solutions of tissue-fibrinogen, and I shall then bring these into connexion with the results obtained by Groth by injections of leucocytes into the blood. I may say that I am only concerned here in putting before you the main facts of my work on the subject. The actual experiments and the general details I have already communicated to the Royal Irish Academy, and the paper has just appeared in their Proceedings.[6]

The injection of a solution of tissue-fibrinogen into the vessels is followed by an increase of the coagulability

[4] This term would appear to be a more appropriate one than tissue-fibrinogen, since this proteid appears to occur not in the inter cellular substance of tissue, but in the cells themselves. It appears also to be more widely distributed in free cells than in cells which are found in tissues.

[5] According to Rauschenbach's researches the plasma has the power of disintegrating not only leucocytes, but many other varieties of animal and vegetable cells.

Digitized by Google

of the blood, which is at its height immediately subsequent to the injection. If the quantity of tissue-fibrinogen injected is large enough, the increase of coagulability leads to the immediate occurrence of intra-vascular coagulation. The coagulation which occurs under these circumstances in the case of the dog occurs only in the portal vascular area; but I have been able to show that we can determine it to any predetermined vascular area by increasing the venosity of the blood in the veins of that particular district, or we can generalise the coagulation and obtain it all over the vascular system, both in the arteries and the veins, by increasing the amount of CO_2 in the blood generally. These alterations in the direction of the "positive phase of coagulation," to use Wooldridge's convenient expression, form, however, only a part of the effects which result from the injection of a solution of tissue-fibrinogen.

We have further to deal with a negative phase of coagulation—i.e., with a condition of diminished coagulability brought about by injections of tissue-fibrinogen. This diminished coagulability was described by Wooldridge in connexion with the blood of the extra-portal vascular areas, where intra-vascular coagulation had occurred in the portal system. I have, on the other hand, I believe, succeeded in establishing that the negative phase of coagulation is due to a general reaction of the system to the injection of tissue-fibrinogen, and that it is possible, by slow injection of moderate amounts of tissue-fibrinogen, to obtain a general diminution instead of a general rise of coagulability. The blood has, therefore, the power of breaking down tissue-fibrinogen into some substance or substances which condition the loss of coagulability. I will here adduce from my note-books an experiment, which seems to me to establish distinctly the sequence of events which I have just described.

EXPERIMENT 1.

Dog 119.—Cannulas inserted into the jugular vein and the carotid artery, and animal anæsthetised with a mixture of ether and chloroform. Samples of blood drawn off from the carotid to determine the condition of coagulability. Sample 1 (5.43 P.M.): Can invert tube at 5.51 P.M.; time, 8 minutes. Ran in 10 cc. of tissue-fibrinogen solution at 5.43 P.M. Sample 2 (5.44 P.M.): Still liquid 1 hour after. Ran in 10 cc. more of tissue-fibrinogen solution. Sample 3 (5.45 P.M.): Still liquid 1 hour after. Sample 4 (5.46½ P.M.): Still liquid one hour after. Sample 5 (5.48 P.M.): Still liquid 1 hour after. Ran in 10 cc. more tissue fibrinogen. Sample 6 (5.50 P.M.): Can invert tube at 5.58 P.M.; time, 8 minutes. Sample 7 (5.51 P.M.): Can invert tube at 6.4 P.M.; time, 13 minutes. Ran 10 cc. more at 5.52. P.M. Sample 8 (5.53 P.M.): Can invert tube at 6 P.M.; time, 7 minutes. Ran in 10 cc. more at 5.54 P.M. Sample 9 (5.55 P.M.): Can invert tube at 6 P.M.; time, 5 minutes. Ran in 10 cc. more. Sample 10 (5.56 P.M.): Can invert tube at 6 P.M.; time, 4 minutes. Ran in 10 cc. more. Sample 11 (5.58½ P.M.): Can invert tube at 6.2 P.M.; time, 3½ minutes. Sample 12 (6 P.M.): Can invert tube at 6.4 P.M.; time, 4 minutes. Sample 13 (6.2 P.M.): Can invert tube at 6.9 P.M.; time, 7 minutes. Sample 14 (6.7 P.M.): Can invert tube at 6.14½ P.M.; time, 7½ minutes. Ran in 20 cc. more tissue-fibrinogen solution. Sample 16 (6.14 P.M.): Can invert tube at 6.16 P.M.; time, 2 minutes. Sample 17 (6.16 P.M.): Can invert tube at 6.20 P.M.; time, 4 minutes. Sample 18 (6.19 P.M.): Can invert tube at 6.22 P.M.; time, 3 minutes. Sample 19 (6.22 P.M.): Can invert tube at 6.26 P.M.; time, 4 minutes. 6.26 P.M.: Clamped the trachea to increase the coagulability of the blood, and ran in 20 cc. more tissue-fibrinogen solution. Death occurred instantaneously, and both sides of the heart and the whole of the aorta were found occupied by a solid clot. No clot in the portal vascular area. Urine gave a very distinct biuret reaction.

We have thus proved that the positive and the negative phase are successive in time, and it was evident that the positive phase is associated with the presence of tissue-fibrinogen, as such, in the blood. It still, however, remained to be determined to what the negative phase of coagulability is due, and I have ventured in my paper referred to above to suggest that it is due to the presence in the blood of albumoses which have been split off from the tissue-fibrinogen by the action of the blood. The evidence upon which I based that suggestion is as follows: (*a*) The plasma from the negative phase areas no longer contains any of the injected tissue-fibrinogen. (This, I may remark, is an observation which was made by Wooldridge.) On the other hand, the blood of the negative phase areas was found by me to have acquired the characters of peptone or albumose blood—that is to say, it clots with CO_2, and on dilution. Coagulation can also be inaugurated in it by an addition of lime salts or of tissue-fibrinogen or leucocytes. Further, (*b*), there is a very close analogy between the distribution of the areas of the positive and the negative phase after tissue-fibrinogen injections and the distribution of coagulability after injections of peptone. For instance, the coagulability is in the case of tissue-fibrinogen injections increased up to the coagulation point in the portal area and to a lesser extent in the venous system generally. Similarly in the case of peptone injections the coagulability is retained in the venous system, and especially in the portal venous system, long after it has been lost in the arterial system. Again, the positive phase after tissue-fibrinogen injections can be extended to the arterial system by rendering the blood there venous; and I have been able to show we have something quite similar in the case of peptone injections, for it is only necessary to render the arterial blood venous in order to restore its lost coagulability to it. Lastly (*c*), I would point out that an excretion of albumose or peptone occurs both in the dog and in the rabbit after the injection of tissue-fibrinogen into the veins or into the subcutaneous tissue. Here, again, I think we have evidence that the tissue-fibrinogen is broken down into albumose in the system.

On the whole, therefore, I think we may perhaps regard it as pretty well made out that the occurrence of a negative phase after tissue-fibrinogen injections stands in some close relation with the liberation of albumose by the disintegration of tissue-fibrinogen in the blood.

(To be concluded.)

ON IRREDUCIBLE DISLOCATIONS OF THE GREAT TOE AND OF THE THUMB SUCCESSFULLY TREATED BY OPERATION.

BY JORDAN LLOYD, M.S., F.R.C.S.,
LECTURER ON OPERATIVE SURGERY IN QUEEN'S COLLEGE, SURGEON TO THE QUEEN'S AND CHILDREN'S HOSPITALS, BIRMINGHAM.

THE analogies seen in the following two cases lead me to report them together.

CASE 1. *Dislocation of great toe backwards; unsuccessful attempts at reduction; operation; recovery.*—William G——, aged forty years, groom, was admitted into Queen's Hospital, Birmingham, under my care, on June 18th, 1889. Shortly before admission a horse he was riding slipped on a granite roadway and fell on its side, with the patient's right foot beneath it. The man says that his heel came first to the ground, and that the whole weight of the horse came on to the toe of his boot with the foot in a vertical position. The sole of the boot was bent transversely across towards the front of the limb. The pain of the accident was exceedingly severe, and he was unable to stand. On admission the right great toe was found completely dislocated on to the back of the metatarsal bone; it was slightly abducted and was flexed at the phalangeal joint. It could be moved laterally without much pain. The rounded head of the metatarsal bone projected prominently in the sole of the foot, the skin being stretched tightly over it. There was already a great deal of effusion into the tissues. The diagnosis of the injury could be made without any difficulty. Chloroform and ether mixture was given by the house surgeon, and attempts made at reduction by traction and manipulation in all directions. I first saw the man on the following day, and although the parts were much more swollen recognition of the exact nature of the case was quite easy. The limb was thoroughly cleansed with hot water, soap, and turpentine, and an anæsthetic again administered. All attempts at reduction being unsuccessful, the limb was made bloodless by elevation, an elastic tourniquet applied, and a two-inch vertical incision made, with its centre over the head of the metatarsal bone, which lay immediately beneath the skin. The head of the bone was found to have thrust itself between the heads of the flexor brevis pollicis muscle, the internal head of

Digitized by Google

which was about half torn across. The anterior ligament with its embedded sesamoid bones was torn away from the metatarsal bone, and had "shut back" behind the rounded head, constituting itself the chief, if not the entire, obstacle to reduction. The tendon of the flexor longus pollicis lay on the inner side of the metatarsal bone. With the parts exposed before me I was unable to reduce the displaced bone until I had completely divided the anterior metacarpo-phalangeal ligament and the sesamoid bones by a free vertical incision made in their middle line. Reduction was then effected at once, but the dislocation just as easily recurred. The wounds between the sesamoid bones, the capsule, and the muscle were sutured closely with catgut, and reduction then remained permanent. The tissues around were infiltrated with coagulated blood. No vessel was tied at the operation. The parts were dusted with powdered boracic acid, a small drainage-tube introduced to the deepest crevice in the wound, the skin brought together with wire sutures, and a dry absorbent dressing applied. The limb was put up on a Nevill's splint, to which it was firmly fixed by strapping, and swung in a Lawrence's cradle.—June 26th: Wound dressed for the first time; perfect primary union; tube and sutures removed. Temperature 98·2°; pulse 70.—July 13th: Wound dressed again and found absolutely well, with skin pale and shrivelled and toe in perfect position. No attempts at movement were ordered to be made. The limb was put up in plaster-of-Paris, and the patient was sent home. A few weeks later all the dressings were discontinued, and the man returned to his work without feeling any inconvenience from his injury.

CASE 2. *Unreduced dislocation of thumb backwards; operation four months afterwards; cured.* — Elizabeth N—— aged seven years, was admitted into the Birmingham Children's Hospital, under my care, on Nov. 27th, 1890. From the mother I learnt that about four months previously the child had slipped, and in falling had caught her right thumb against the side of the door. She felt great pain at the time, and was at once taken to the Birmingham General Hospital, where she was seen by a junior officer, who kept her under observation and treatment for more than two months. What treatment was adopted or what opinion was given I could not satisfactorily elicit from the mother, but she seemed very much surprised when I told her that the child's thumb was "out of joint." On admission the thumb was found completely dislocated backwards. The head of the metacarpal bone projected markedly forwards, and was covered by a resistant layer of soft parts. The base of the first phalanx lay behind the metacarpal head, and was slightly abducted. The phalangeal joint was semiflexed and readily movable. When the child closed its fist the thumb stood straight outwards, and could not be brought anywhere near to the flexed fingers. No pain had been complained of for several weeks. On Dec. 1st, the limb having been previously sterilised and an Esmarch's tourniquet applied, I made a two-inch incision over the front of the metacarpal head in the line of the thumb. Below the skin the bone was covered with newly organised fibrous tissue, which was divided, and the articular surface of the metacarpus exposed. The phalanx lay completely behind the metacarpal bone, and had attached to its base the anterior metacarpo-phalangeal ligament which had been torn from its upper attachment, and had "shut back" behind the metacarpal head. The heads of the flexor brevis pollicis muscle had been torn apart, and lay posteriorly to the metacarpal bone, where they had become attached by newly formed fibrous tissue. The anterior ligament was freely divided vertically at its middle, and, after a few fibres of the internal head of the short flexor had been divided transversely, reduction was with little difficulty effected. The tendon of the long flexor was not seen; it certainly did not lie between the bones. Displacement after reduction easily recurred, but was overcome when the divided ligament and muscle were sutured together in front of the metacarpal bone. No vessels were tied. The wound was dusted with powdered boracic acid, and dressed with dry absorbent dressings without drainage. The limb was put up with the phalanges acutely flexed towards the palm, the fingers bent over them, "fist like," and the whole hand firmly bound with bandage. The arm was carried in a sling, and no splint of any kind applied.—Dec. 7th: Wound dressed for first time; perfect primary union; all sutures removed. Temperature 98·4°; pulse 82. — 20th: Wound dressed again; quite well; thumb in perfect position, with a little movement of flexion and extension.—27th: Made out-patient, merely wearing a thumb-stall, and without any tendency to return of the deformity. I saw the child a few weeks later, and improvement was still going on, but there was slightly limited movement in the joint when compared with the other limb.

Several theories have been advanced as to the cause of the irreducibility in this class of injury. The one most generally accepted, and the one still taught in most of our modern text-books, is that it depends upon the tight embrace of the two heads of the flexor brevis pollicis muscle, between which the metacarpus is supposed to be thrust as through a button-hole. A point of greater importance, however, lies in the fact that the head of the bone pushes its way through the muscle above the level of the sesamoid bones, the anterior metacarpo-phalangeal ligament being at the same time torn away from its metacarpal attachment, and these two structures, which are closely incorporated with each other, "shut back" behind the protruding head and become closely applied to the anterior part of the articular surface of the displaced phalanx. The "shutting back" of these structures is due partly to their own elasticity and partly to the pull of the remaining attachments to them of all the short muscles of the thumb or great toe. In the first of the above cases the inner head of the flexor brevis pollicis was to some extent torn across, and the neck of the metacarpus was only loosely held by the sides of the rent through which it passed; but the sesamoid bones lay between the base of the phalanx and the back of the misplaced head, and constituted in themselves the sole obstacle to reduction, and when these structures were split vertically the head slipped back to its proper position with the greatest ease. A precisely similar condition existed in the second case. An excellent description of this arrangement of parts was given many years ago by Dr. Lauric.[1] He says: "The end of the metacarpal bone is driven completely through the inner fibres of the external head of the flexor brevis muscle. The anterior ligament is completely torn from the metacarpal bone, and remains attached to the phalanx and sesamoid bones in such a manner that the torn ligament and the sesamoid bones are carried backwards by the phalanx and placed between it and the metacarpal bone. The state of parts is aggravated and rendered permanent by the contraction of the muscles attached to the sesamoid bones and the anterior ligament. The result is that the opening in the ligaments by which the metacarpal bone escaped is thrown back nearly half an inch, and the remains of that ligament and sesamoid bones form a partition between the displaced ends of the bone which forms a mechanical obstacle to the reduction."

Mr. J. C. Wordsworth published a paper in THE LANCET (vol. ii. 1863, p. 443) on "Dislocations of the Thumb at the Metacarpo-phalangeal Joint," showing that the difficulty in reducing them arises from malposition of the tendon of the long flexor. He describes three cases, one of which "was irreducible, and here the long flexor tendon was found between the ends of the bones, having passed round the ulnar side of the head of the metacarpal bone, and by traction having been drawn across the joint." It is possible that Wordsworth's explanation may be the true one in a few cases, but the peculiar displacement of the long tendon between the bones will not be found in all these irreducible dislocations.

The first of my cases is of especial interest, because of the rarity of the accident in the foot, and because, so far as I can ascertain, it is the first dislocation of the great toe which has been treated by open operation. Its likeness in every detail to the analogous injury of the thumb was conspicuously striking, and its treatment by open incision in an exsanguineous limb was simple and satisfactory. The second case is chiefly of interest because of the length of time—four months—which intervened between the accident and the operation. Although much organisation had gone on in the damaged tissues, it was still possible without great difficulty to effect a return of the dislocated bone. It is worth noting, too, how readily displacement recurred in both cases, and how completely this was overcome by closely suturing the opening in the flexor muscle and between the sesamoid bones. This procedure is better than that of excision of the extruding metacarpal head, as has been sometimes recommended. Mr. G. R. Turner read a paper before the Clinical Society of London (Mar. 9th, 1888) on "A Case of Dislocation of the Thumb backwards, in which excision of the head of the metacarpal bone was

[1] Medical Gazette, vol. xxi., 1837, p. 93.

Digitized by Google

practised eleven days after the accident." The usual anterior incision was made, and "the lateral aponeuroses of the short flexor divided. The main obstacle to reduction was found to be the flexor longus tendon, which had slipped inwards. Dislocation was reduced, but easily recurred. The head of the bone was therefore excised and a good recovery followed." Although there is now but little danger or difficulty in excising the metacarpal head, it appears to me that recurrence can be prevented in the manner adopted in my own cases, and that excision therefore is altogether unnecessary.

Birmingham.

A NEW TREATMENT OF ACUTE GONORRHŒA.

BY C. E. COTES, B.A., M.B. CANTAB., F.R.C.S.,
SURGEON (OUT-PATIENTS), LONDON LOCK HOSPITAL; DEMONSTRATOR OF ANATOMY, ST. GEORGE'S HOSPITAL.

WITH A NOTE ON THE ACTION OF THIS TREATMENT, AND OF SOME ANTISEPTIC INJECTIONS ON THE GONORRHŒAL DISCHARGE,

BY CHARLES SLATER, M.A., M.B. CANTAB.,
LECTURER ON BACTERIOLOGY, ST. GEORGE'S HOSPITAL.

NOT feeling at all satisfied with the results of the various treatments of acute gonorrhœa usually adopted, I devised the following method. The patient is first made to micturate, and thus remove the discharge from the urethra as far as possible. The endoscopic tube, warmed and oiled, is then passed into the urethra, the patient lying on a couch. As a rule the passage of the instrument gives rise to but slight pain, but occasionally in sensitive patients, or where inflammation is very acute, a 10 per cent. solution of cocaine previously injected up the urethra will be found useful. The urethra is then thoroughly mopped with dry cotton wool fixed in a stilet and examined by the electric light. The exact limit of the inflammation can then be clearly seen. It is, as a rule, quite five inches from the meatus; it may be four inches even so early as the third day of the disease. The implicated surface is at once to be recognised by its swollen, bright-red appearance, as contrasted with the rosy colour of the healthy urethra. Occasionally distended vessels can be seen coursing over the inflamed surface. It is important not to pass the endoscope needlessly far beyond the posterior limit of inflammation, which is usually sharply defined. The diseased membrane should be now carefully remopped with dry cotton wool, so as to remove every vestige of secretion and have a perfectly clean surface. A mop of cotton wool on a stilet, and charged with a solution of silver nitrate (ten grains to the ounce of water), should then be passed down the endoscopic tube and thrust through its distal aperture. The tube and the mop are then withdrawn simultaneously. By this means the walls of the urethra contract upon the mop and are thoroughly moistened by the solution. For the two inches of the urethra near the meatus a fresh mop is used, so as to completely saturate this portion of the passage, in which the disease commences, and where also the inflammation is most intense. The patient will always complain of slight burning pain for a few minutes; but this gradually passes off, and in ten minutes or so he feels quite comfortable. He is recommended to take a hot bath at night and to remain quiet, in bed if possible, the following day. The diet is regulated as usual. A saline purgative, with an alkaline or copaiba mixture, is given internally, and the patient is instructed to use a mild cleansing injection, such as Condy's fluid (one drachm to the pint). But it should not be left to his unaided discretion to accomplish this task for himself. There is art even in such a slight proceeding as the administration of an injection. The injection is required to clean the diseased passage, not to distend the canal violently throughout its whole length. A glass syringe with a bulbous nozzle holding *only* two drachms is used. The patient, having micturated, should fill this syringe with hot water, and, removing any air that remains, insert the nozzle between the lips of the meatus, keeping it on the floor of the urethra and pressing these lips from side to side on to the nozzle. He now carefully empties the syringe up the urethra. As the meatus is a vertical slit, if he presses the lips on to the nozzle vertically the aperture will gape, and so the injection will escape by the side of the nozzle and not pass up the canal. Hence the importance of lateral pressure. This warm water is simply intended to clean out the passage. Now he takes the medicated injection and uses it in a similar manner, only this time he removes the syringe but keeps the injection up the urethra quite half a minute by pressing tightly the lips of the meatus. As regards the frequency of injection, the oftener the better. I always recommend quite six times a day, but not the last thing at night time, as the distension of the canal which may result predisposes to chordee. I use only a two-drachm syringe, for after many experiments I have proved that this amount of fluid, when injected into the urethra after death distends the canal completely for rather more than four inches. If this amount be injected into an inflamed and thickened urethra, not to mention its tendency to spasm, more of the urethra must be distended, and this is not only unnecessary, but for manifest reasons unadvisable.

Forty-two cases of acute gonorrhœa have now been treated by me in this manner. With two exceptions the condition had existed in every case for many days, and in several instances was associated with severe chordee. The average time taken before these patients were well was a little under twelve days. As this duration is calculated from the date of the beginning of treatment to the date of the first visit at which the patient was found to be quite free from discharge, the above average result is somewhat in excess of the true time before cure, for more than one patient has stated that he had been already well for two or three days. Early cases, as might be expected, are more amenable to treatment than those which have been established for some time. Two of the forty-two cases attended to were of two days' standing only. In each the inflammation was intense, and had extended backwards about four inches. The urethra was lined with thick purulent discharge clinging to the walls, and so difficult to remove that it certainly would not have been washed away by any injection. The discharges were well mopped away, and the patients treated in accordance with the method described. The result was in each case a complete cure in five days, without a single annoying or bad symptom. Cured cases have been examined with the endoscope, and a perfectly healthy and normal urethra was invariably found. The immediate effect of the treatment is to produce a fairly free purulent discharge during the first twenty-four to forty-eight hours. The pus is thick, and often stringy and very tenacious. The discharge rapidly diminishes in amount after this time, often being quite slight in four or five days. It is watery in appearance, and usually disappears entirely in seven or ten days. From the time the treatment is adopted the patient is quite free from scalding on micturition, and should he have suffered from chordee, the dilatation of the urethra which the treatment entails diminishes, and often abolishes, that terrible complication.

From these results it seems clear that the treatment compares most favourably with the ordinary treatments, for under it gonorrhœa becomes a quite curable disease in a limited time, and does not result necessarily in that only too prevalent disease, gleet. It is not an abortive treatment in the old sense of the term, when powerful caustics were applied blindly and, as a rule, unsuccessfully. The idea of the abortive treatment was, however, less in fault than the method of its execution, and most of the objections to it would be removed if the technique I have advocated had been employed. It is not suggested that a discovery has been made by which every case of acute gonorrhœa can be conducted to a rapid and satisfactory conclusion. There are two classes of cases which cannot be treated successfully by this method: namely, those in which the meatus is abnormally small, so that the passage of the endoscope is impossible; and those in which the disease has extended so far back that it is out of reach of the application. The strength of the solution of silver nitrate may be modified as experience dictates, and the question of a second application will sometimes arise. In none of the forty-two cases has this been found necessary.

The main points of the treatment are: 1. The treatment rests in the hands of the surgeon instead of being left to the patient. 2. The urethra can be thoroughly cleansed, so that there is no doubt that the remedy is applied directly to the affected mucous membrane. Examination of the

Digitized by Google

urethra by the endoscope immediately after micturition and injection almost always shows that there is still a thick coagulated discharge adherent to the walls, indicating the mechanical difficulty an injection would have had in acting directly on the mucous membrane. 3. The exact extent of the inflammation can be seen, and the remedy applied to its extreme posterior boundary. 4. The remedy is applied to the urethral walls when they are distended and stretched by the endoscopic tube, so that all furrows are obliterated. 5. Stronger applications can be used with safety because the remedy is no longer applied blindly or by unskilled hands, and I have no hesitation in saying that the use of the endoscope allows play for a good deal of delicacy in touch. 6. There is no fear of the application carrying the infected material to the distal part of the urethra, and thus giving rise to complications.

BACTERIOLOGICAL NOTE.

Previous to the employment of the treatment described above trials were made of the value of some antiseptic injections. These were not found, however, very satisfactory, whether regarded from the clinical or bacteriological point of view. Of those injections usually employed, a large number, such as the salts of zinc and lead, boracic acid, sodium salicylate (5 to 20 per cent.), and carbolic acid (1 per cent.), have practically no bactericidal action. Corrosive sublimate in solution of 1 in 20,000 and 1 in 10,000 was shown by Friedheim in the Breslau clinic to be actively antiseptic, but decidedly irritating; the latter strength, indeed, produced intense inflammatory symptoms. Our own experience, while confirming to a certain extent these observations, leads us to attribute both less antiseptic power and less irritating action to the perchloride. The solutions employed were much stronger than the above—viz., one grain to six ounces (about 1 in 2000), two grains to six ounces (about 1 in 1300), and three grains to six ounces (1 in 860). No toxic or inflammatory complications occurred.

For microscopical examination the urethral secretion was collected as pure as possible, spread on a cover glass, fixed, stained with Löffler's methylene blue, and examined with a high power ($\frac{1}{12}$ oil immersion). The examinations were continued for a long time, usually at intervals of from three to six days. With the 1 in 2000 injection the patients experienced a little pain with the first injections, but this soon passed off, and the scalding on micturition was greatly diminished. There was no rapid change in the character of the secretion, which gradually decreased as the case progressed. Microscopically, the discharge became slowly less purulent, and at an early stage the proportion of young epithelial cells to pus cells increased. The gonococci steadily diminished in number and became less typically distributed, but after the lapse of so long a period as thirty-eight days could still be demonstrated. The cases lasted on an average from six to eight weeks, but many patients had still a slight gleet when they ceased to attend the hospital.

With the 1 in 1300 injection better results were obtained. This injection gave rise to no more pain than the weaker solution, and had a more decided effect on the micro-organisms. In several cases the cocci had disappeared in from fourteen to twenty-one days. The changes in the microscopic appearance of the secretion were similar to those following the 1 in 2000 injection, but took place more rapidly. The average duration of the cases was forty days, but during the last ten or fifteen days the discharge was hardly perceptible. The 1 in 860 solution proved too irritating, and did not show any superior bactericidal action over the 1 in 1300 injection. Thinking that some of the lack of success with these injections was due to the formation of a coating of coagulated albuminous material which protected the micro-organisms from the action of the antiseptic, a 1 in 1000 solution of iodide of mercury and sodium was employed. This, however, caused very considerable pain, did not diminish the scalding, and did not appear to be of such value, either clinically or microscopically, as to warrant a persistence in its use. Silver nitrate in solution of from 1 in 4000 to 1 in 2000 was the injection selected as most efficient by Friedheim, and was said to rapidly diminish the number of micro-organisms, and by its astringent action to aid the cure. Such solutions have been long in use at the Lock Hospital, but have for some time been given up as being clinically a failure. The difficulty of destroying the micro-organisms associated with gonorrhœa has long been recognised. This difficulty is not due to the resistance of the gonococcus; it is indeed easily attacked by destructive agents, but apparently is due to the impossibility of reaching it by means of injections. It is well known that though the gonococcus acts at first quite superficially, yet it rapidly passes into the deep layers of the mucous membrane and into the submucous tissue, where it is shielded from the action of antiseptics and covered by a dense layer *of* purulent discharge. It became obvious from the attempts recorded above, as well as from frequent examinations of the urethra after injections, that to be effective the medicament must be applied in some way which would permit of the perfect cleansing of the urethra from discharge, and render it certain that the solution reached the inflamed mucous membrane. The method devised by Mr. Cotes realises these conditions. The question of the specificity of the gonococcus does not affect the *rationale* of the treatment, since, whatever opinion is held on this point, there is no doubt that Neisser's micro-organism is present in and associated with the purulent urethritis of gonorrhœa.

The effect of the new treatment on the character of the discharge is at once very marked. Examined microscopically, the discharge during the first twenty-four hours after treatment is often chiefly purulent, but in many cases even in so short a time as this there is considerable alteration in the relative number of the pus and epithelial cells. These latter increase rapidly, so that in forty eight hours a specimen of the discharge has the appearance met with during the third or fourth week in cases by injection. Indeed, in some cases treated early, the discharge at the end of two days consists almost entirely of epithelial cells of various types with a small admixture of pus cells. There is, in addition, a certain amount of exudation, so that the cells are found entangled in a fibrinous material. The effect on the cocci is very marked also. They are very considerably diminished in number in twenty four hours, and when met with are often free in the exudation or attached to the epithelial cells, while scanty in their usual situation in the interior of the pus cells. This diminution of the cocci goes on rapidly, and their absence from the pus cells and their presence free or in epithelial cells become more marked. In some cases no gonococci can be found forty-eight hours after treatment, and in nearly all cases they are absent after seven days. It is obvious that the local application of silver nitrate solution has a very powerful effect in causing the elimination of the micro-organisms, and that, whether regarded clinically or microscopically, this treatment is most efficient.

ON A CASE OF

HEREDITARY SUPPRESSION OF FINGERS,

AND THE RELATION OF THIS KIND OF DEFECT TO CROOKED LITTLE FINGER, WITH REMARKS ON THE DISAPPEARING LITTLE TOE.

BY R. CLEMENT LUCAS, B.S., M.B. LOND., F.R.C.S.,
SURGEON TO, AND LECTURER ON ANATOMY AT, GUY'S HOSPITAL; SENIOR SURGEON TO THE EVELINA HOSPITAL FOR CHILDREN.

IN the Guy's Hospital Reports for 1880–81 I described a remarkable family, in which there existed an apparently irrepressible tendency to the production of supernumerary digits—a proclivity so strongly marked that out of a total of eighty descendants traced from a particular individual no less than twenty-four, or 30 per cent., presented supernumerary fingers or toes, and this without any reinforcement by the intermarriage of relatives. In that short paper I incidentally mentioned two other deformities which had attracted my attention by their tendency to hereditary transmission; one of these was harelip and cleft palate, the other the simple and very common defect of a crooked little finger. In the particular family referred to a new defect had made its appearance in one individual in the shape of cleft palate and harelip combined, which, in tracing the family history, I found had been foreshadowed by a harelip which occurred in a great-uncle. With my mind bent on the observation of minor defects which might foreshadow graver evils for future generations, I began tracing back from the greater pronounced deformities to discover anything of a milder nature in the parents or ancestors which might indicate that a particular deformity would be likely

Digitized by Google

to appear, and I discovered, in reference to cleft palate, that the congenital absence of a lateral incisor tooth of the upper jaw in a parent might foreshadow the greater deformity in the offspring. Three observations bearing on this were recorded in the Clinical Society's Transactions for 1888. Now the other minor defect to which I alluded in the paper of 1880—viz., a crooked little finger—has never forced its importance upon my mind until within the last few months. I said in the paper referred to that I had frequently traced this defect through three generations. It is exceedingly common, this congenitally bent little finger, and therefore is probably in the main merely a general expression of the tendency to suppression of the digit which is so little used, and which is constantly cramped by a large proportion of the population for many hours during the day in the occupation of writing.

That this is the probable explanation of the origin of the defect is borne out by the fact that the little finger when presenting this congenital bend is frequently also abnormally short. Further, the defect of the little finger may not be a mere flexion, but be accompanied by a lateral displacement of the terminal phalanx; or this slight lateral displacement may exist alone, or be associated with a shortened finger. If, as I suggest, the commonly found crooked little finger is but an expression of hereditary neglect brought about by little use and cramped position, it will bear an interesting relation to the fast disappearing little toe. This latter useless little appendage, which is almost as much out of date as the pineal gland, has got before the anatomy books in its downward descent under generations of boot pressure. It has long since lost one of its extensor tendons; so that, if perchance a second one be now found, it is recorded by enthusiastic young anatomists as an abnormality. The flexor tendons are, however, still described as two in number; but so common is the suppression of one of these that a perfect and complete development of two flexors is, I am inclined to believe, falling into that interesting heap of cast-off anatomy amongst which anatomists dig up the homologues of their abnormalities. I am interested to see that Professor Macalister, in his work, states that the second and third phalanges of the little toe are, after a certain period of life, commonly found ankylosed, which is a further proof of the downward descent of this appendage. The future of the human foot would appear to be a gradual suppression from without inwards of the toes, and a further strengthening of the great toe line on the inner side. That this is all that is required is abundantly proved by observing the thousands who, even at the present time, use only the great toe as a means of progression. I was much interested some few years ago by observing the foot of one of the finest athletes of the day. He was an All-England three-quarter at football, a champion short- or mid-distance runner, and the finest football kick of his day; yet he wore a boot so narrow that only the great toe could approach near to the end of it. All this brilliant performance was done by the great toe alone, and he showed on the running path and in the football field that swiftness, agility, and strength were, so far as the foot is concerned, centred in the line of the great toe. The enormous and increasing power of the great toe tendons is further illustrated by the feats of the ballet dancer, and a *première danseuse* would without doubt be soon hissed off the stage if she were seen to balance herself on any part of the foot other than the great toe. There are still some anatomists I believe who affect to be enamoured of the beauties of the savage foot, but its picturesqueness never appealed to my imagination. It is a long-toed, long-heeled, low-arched splay foot, useful no doubt to prevent the limb it supports from sinking too deeply into the native sands, or to aid the hands in upward-tree progression, but as distinct from the civilised foot as the huge hoof of the Shire horse is from that of the thoroughbred. At present the great-toe line of support is apt to rebel against the undue strain put upon it, and gout and osteo-arthritis attack the most used joint of this series at a time antecedent to their appearance in other joints; hence, just as Her Majesty is said to be the most overworked woman in the realm to which hereditary responsibility has fitted her, so the metatarsal phalangeal joint of the great toe, from its responsibility, must be regarded as a queenly joint at present not quite equal to the strain required of it—at least when such strain is associated with a queenly table. So, too, the beautiful longitudinal arch on the inner side of the foot, in weakly, fast-growing lads, and especially when the age of puberty bears a relation to immoral practices, yields under the superimposed burden, and there is a reverain to a lower type and a less elastic tread. But a more general reversion to a lower human type is brought about by syphilis and rickets, which may thus be regarded as debasing diseases, for either of these in hereditary transmission is apt to lead to stunted growth, an ill-shapen head and a flattened nasal bridge, conditions and appearances which are usually regarded as peculiar to a lower type of humanity. But I am straying somewhat from the disappearing little toe and its possible cousinship to the crooked little finger. All the arguments I could adduce in favour of the view that the future of the human foot was a further development of the inner side and a suppression from without inwards of the toes, I put forward in an introductory lecture to my course of Anatomy delivered in 1888; and the idea stimulated the poetic genius of one of our students, who threw the fancy into a rhyme so clever that it may be worth while to reproduce it from the *Guy's Hospital Gazette* of Oct. 13th, 1888:—

"DIGITI MINIMI DECESSUS.

"'*Man is losing his little toe. . . . and can do without it.*'—Mr. Clement Lucas, in his opening lecture.

"If thou must go, thou feeble, foolish digit,
Fain would I speed thy slow degenerate way!
I daily feel a disagreeable fidget
Whenever I've occasion to display
Thy doubtful outline, and thy form chaotic
(Born of a taste in boots, perhaps erotic).
Thou art a shock to my æsthetic sense,
And offerest no kind of recompense
In way of use; of every function shorn,
Except to act as basis for a corn.
When thou art gone I'll still maintain my grace,
Still walk erect wherever I may be;
Still I'll belong to the athletic race,
Waltz with the fair, and kick mine enemy!
So *pace* Schopenhauers, and *pace* Mallocks
When I've acquired a hypertrophied hallux,
To monodactyle type thus simplified,
Life shall be simpler too, and so—beatified.

When future science forgets thee in thy prime,
Methinks a great mind from a northern clime
May then discuss thy remnants, and declare
He finds a true *prophetic organ* there!

F. G. H."

To return to the crooked little finger. I was examining Mr. H. E. G—— for insurance on Nov. 14th, 1891, when I noticed as he presented his hand that the little finger was crooked and short. I asked if there were not others of his family with the same defect, and he replied that his fourth child, a son, had precisely similar little fingers. I pressed him further for his family history as to any similar defects, and after some hesitation on his part I procured the following account. His father and mother he believed to have been perfect, and he knew nothing of their ancestors. His father married twice, and his two half brothers had on each hand the second finger shorter than the third; or, as he put it, the second and third fingers had changed places. Mr. G.'s eldest daughter and second child was born with no fingers on the right hand and a small thumb. One half brother only is married, and he has one child unmarked. I have already alluded to Mr. G——'s fourth child having his father's peculiar little fingers. One of his father's brothers married his mother's sister, and they had five children, one of whom, a daughter, is married and has an only daughter with a thumb absent on the right hand. Another of his paternal uncles is married, and has a family. His eldest daughter, first cousin to Mr. G——, is married and has three children, of whom the eldest, a boy, has no fingers on the left hand. In this family there is shown to be a peculiar tendency to a shortening or disappearance by suppression in development of particular digits, and it is the first instance I have come across which would seem to indicate that shortened crooked little fingers may lie in close proximity to the more serious deformity of further suppression of other digits. It was the observation of the peculiar little finger that led me to obtain the extraordinary history just detailed. It is now well established that a tendency to the production of supernumerary digits is strongly hereditary, but there is less accumulated evidence as to a like hereditary proclivity in the case of suppression of the fingers or toes. It would seem that nature, having arrived at a tendency to suppression in a particular individual—of which the earliest indication may be a shortened or bent finger,—in some of his descendants may sweep away wholesale the fingers of a hand. There is an obvious reason why there should be less opportunity of

Digitized by Google

establishing heredity in cases of suppression than in superabundance, because in the former the loss is apparent, and is classed by the general public as a deformity to be avoided; whereas supernumerary digits are usually removed by surgeons during infancy, and thus the tendency is concealed.

I am well aware that there is a wide gap of evidence between the suggested origin of the crooked little finger and the establishment of a hereditary tendency to suppression of digits, and it is possible they depend upon two processes so distinct as scarcely to be related. Such suppression as occurs from disuse through generations upon generations, or through ages upon ages, and which I maintain can be shown to be taking place in the case of the little toe, is so gradual and so general that any idea of deformity is completely enshrouded by time. It is only when we observe an abrupt suppression in development that we regard the result in the light of deformity. When such tendency exists, no doubt in-breeding would increase and perpetuate the defect; and it is not improbable that in families where several well-marked instances occur there may have been an accidental union in the parents of two individuals, each with a slight deviation from normal in the direction of the result produced. Hence the importance of observing minor defects which, increasing by generation, may be pregnant with graver deformities in the unborn future.

Finsbury-square, E.C.

THE CONTINUOUS ADMINISTRATION OF OXYGEN IN A SEVERE CASE OF BRONCHO-PNEUMONIA FOLLOWING INFLUENZA; RECOVERY.

BY WILLIAM COLLIER, M.D., M.R.C.P. LOND.,
AND
HORATIO P. SYMONDS, F.R.C.S. ED.

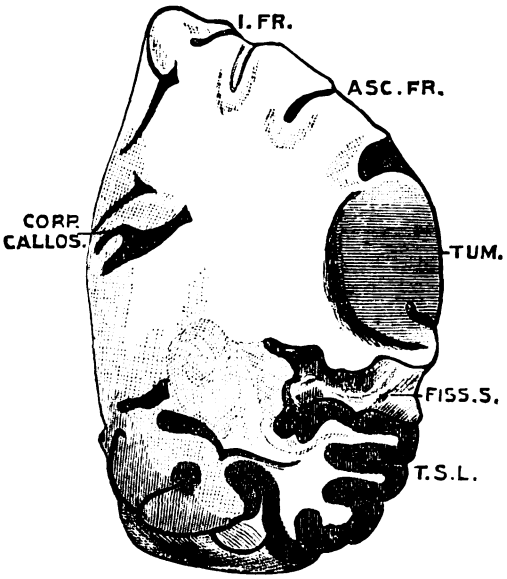
THE patient, a lady aged fifty-seven, was attacked with influenza about the middle of January of the present year, from which she was recovering, when, on Feb. 1st, a relapse set in, accompanied by the development of lung symptoms, which gradually increased in severity. On the morning of Feb. 5th her condition was as follows:—Slightly cyanosed. Temperature 101·4; pulse 108; respiration 30. Urine free from albumen. She was troubled with a most persistent dry cough, unattended with expectoration, which had been kept in check by the inhalation of the chloroform mixture described in THE LANCET of Jan. 30th. Over the lower half of the lungs, both anterior and posterior aspects, abundant sharp large and small crepitations could be heard. In addition, near the inferior angle of the scapulæ on either side the breathing was bronchial in character, especially so on the right. At 9 P.M. the same day the temperature was 100°; pulse 96; respiration 38. The following morning the patient was decidedly more cyanosed, the respiration had increased to 40 per minute, and her pulse was weaker. On Sunday, Feb. 7th, her condition remained stationary. In the region of the inferior angle of the right scapula the breathing had now become tubular in character and the percussion note dull. A patch of dulness with bronchial breathing was detected over the base of the left lung. On this day we agreed to try the effect of oxygen, and gave it for short periods, with the result of slightly diminishing the cyanosis and improving the pulse. On Feb. 8th (the following morning) the patient was decidedly worse. Her respiration had increased to 50 per minute; pulse 120; cyanosis much more marked. She was lying in a drowsy, semi-conscious condition, unable to sleep on account of the dyspnœa. She had voided very little urine in the past twenty-four hours, which contained a heavy cloud of albumen. We now decided to push the oxygen and to administer citrate of caffeine hypodermically. A good stream of oxygen was turned on, the mouth piece being held well over the mouth. At the end of twenty minutes the respiration had fallen from 50 to 40, the pulse from 120 to 106, and it had improved in character; the lips had assumed a ruddy in place of a purple tint, and the patient was dozing calmly. The stream of oxygen was now diminished and the nurse instructed to keep a small quantity playing over her mouth during the day. At our evening visit we found that she had rested more calmly throughout the day, and that the cough had apparently been much benefited by the oxygen. Her general condition, however, gave us much anxiety, as the rapid improvement of the morning had not been maintained, and it was clear that the mischief in the lung had in no way abated. The nurse was instructed to continue the oxygen throughout the night. On our arrival on the morning of Feb. 7th we found the patient in a critical condition. She was quite unconscious of her surroundings, and could with difficulty be aroused; the cyanosis had much increased; pulse 120; respiration 45. On inquiry, we found that our oxygen cylinder had become exhausted at 3 A.M., and that the patient had been without any for six hours. Two hours and a half later we were enabled to borrow a cylinder in the town, and at once recommenced the administration. She was next seen in the afternoon at 3 P.M., when a distinct improvement was noticed. At our evening visit at 9 P.M. the improvement all round was most marked. The temperature had fallen from 102° to 99°; the pulse from 120 to 104; the respiration from 45 to 38. From this point up to the present time the improvement has been continuous and uninterrupted. The administration of oxygen was kept up throughout Tuesday night (Feb. 9th) and Wednesday, after which it was given for short periods, the intervals between the administrations being gradually lengthened as the lungs cleared, so that for the past few days no oxygen has been required. For some days past the patient's temperature has been normal; pulse about 80; respiration 27. The lung symptoms all point to a gradual clearing up of the mischief.

Remarks.—We would point out that up to the time we agreed to administer the oxygen continuously the patient's condition had steadily grown worse, and that she was then in a very critical condition. The continuous administration was immediately followed by unmistakable improvement, as shown by the marked fall in the rate of respiration and pulse and improvement in colour. The oxygen also enabled her to get more sleep and rest than had been the case for some days. Further than this, it had a marked influence on the very troublesome and intractable cough—so much so that after we had given up the continuous administration the nurses were so certain of the relief likely to follow oxygen inhalation that they gave her a small quantity from time to time to check it. The rapid return of all the bad symptoms on the Tuesday morning, when the patient had been without oxygen for six hours, and the equally marked improvement within a few hours of its readministration, appeared to us a crucial test. The conclusion we formed was that for oxygen to be of value in these cases it should be administered more or less continuously. The oxygen cylinders were supplied daily by Brin.

Oxford.

A CASE OF SCIRRHUS OF THE BRAIN SECONDARY TO THAT OF THE BREAST.

BY THOMAS WILSON, M.D., B.S. LOND.,
HON. GYNÆCOLOGIST TO THE WOLVERHAMPTON AND SOUTH STAFFORDSHIRE GENERAL HOSPITAL.



THE following case occurred while I was resident medical officer at the National Hospital for the Paralysed and Epileptic, and has been recalled by the similar case published by Mr. Beadles in THE LANCET of Oct. 3rd, 1891. For permission to publish the notes I am indebted to Dr. Charlton Bastian, under whose care the patient was.

Charlotte M——, aged sixty-eight, was admitted to the Hospital for the Paralysed and Epileptic, Queen-square, London, under the care of Dr. Bastian, on March 1st, 1887, complaining of fits and left-sided paralysis. In November, 1886, the patient had had her left breast removed in St. George's Hospital, and I am indebted to Mr. Bull, at that time surgical registrar, for his courtesy in supplying notes of the case. From these it appears that a large scirrhous growth, extending from the outer margin of the breast into the axilla, was removed, together with the breast, which contained a very small hard growth, by Mr. Dent on Nov. 18th. The axillary tumour could not be entirely removed at the time of operation, and it was thought that recurrence had taken place before the patient left St. George's Hospital for a convalescent

Digitized by Google

home. About a fortnight after Christmas the woman was sitting reading one day, when she suddenly began to feel giddy and sick, and in two or three minutes lost consciousness for a short time. During this attack urine was passed, and on coming to there were vomiting and diarrhœa; no paralysis of any part was observed immediately after this attack. Five or six weeks later the patient was wakened from sleep by a feeling as if something were pricking in the left side of the mouth; she got out of bed, and then twitching began at the left angle of the mouth, followed by twitching in the fingers and thumb of the left hand; then the patient fell down, and her head turned to the left and bumped the floor spasmodically. This attack lasted over an hour, the convulsions being almost entirely left-sided, and there being no loss of consciousness. One or two fits have occurred since this, but the woman does not remember anything about them. The left arm and leg have gradually been getting weak since about Christmas, and the patient has noticed that food tends to collect in the left cheek since a week or two after the first fit. There has been slight headache (not localised); no vomiting, except on one occasion after the first fit, as above described. The patient's health previous to the tumour in the breast had been good. She had borne eight children, one dying of "water on the brain" at four years of age. A sister and a cousin on the father's side had cancers; two brothers died of phthisis; there was no other family history of importance. On admission the woman was dull, taking little interest in what was going on around her, but giving quite rational and clear answers to questions. There was some weakness of the left leg, great weakness of the left arm and at the left angle of the mouth, while the movements of the rest of the left face were decidedly, but not greatly, weaker than those of the right; the faradaic and galvanic reactions were normal and equal on the two sides of the face. The left half of the tongue was also weak, and articulation rather thick and indistinct. The knee- and radius-jerks were active, greater on the left, and there was well-marked ankle-clonus on the left side; none on the right. There were slightly diminished tactile, markedly diminished and altered painful, and much diminished thermal sensations all over the left arm and leg and left half of the face and trunk, the sense of position being also very imperfect in the arm and leg, especially the former. The right plantar reflex was active, the left absent; no other superficial reflex could be obtained. There was no hemiopia or any other affection of any of the special senses. The edges of both optic discs were blurred all round, and there was slight swelling of the papillæ, but no hæmorrhages; the pupils were equal and their reactions normal. The heart's impulse was diffused and fairly strong, and a soft systolic murmur was heard at the apex and over the whole left side of the heart; there were a few dry râles in each lung; the urine contained no albumen or sugar. There was a large scar running upwards and outwards in the situation of the left breast; some thickening was felt in the axilla and a few small hard glands just above the left clavicle and in the left posterior triangle. The left arm was much swollen from the middle of the arm to below the middle of the forearm, the swelling being very solid and not easily pitting for the most part. During her stay in hospital the patient complained of occipital and frontal headache almost every night, and there was a little wandering delirium occasionally. The hemiplegia gradually increased, and became absolute by about March 24th.—April 4th: The temperature has been irregularly raised for three days, varying from 100° to 103°; the woman is very drowsy and mutters a good deal; there is occasional Cheyne-Stokes breathing, and there has been complete incontinence for several days, and considerable tympanites came on three days ago and continues. The left limbs are quite flaccid, the right still preserving their tone. Knee-jerk and ankle-clonus have quite disappeared on the left side, the right knee-jerk being present, though slight. There is no plantar reflex to tickling on either side; to prick of pin the right is still rather greater than the left. The patient gradually became more and more unconscious, and died comatose on April 9th. A few hours before death the left lower limb was observed to be very livid and congested, presenting a marked contrast to the right one, and the day before death the œdema of the left hand and arm, which had been very marked ever since admission, almost entirely disappeared.

At the necropsy, made eighteen hours after death, nothing worthy of note was observed about the calvaria or dura mater. On reflecting the latter, the convolutions over the parietal and greater part of the frontal and occipital lobes on the right side were found to be markedly flattened; over the whole left hemisphere there was considerable wasting of the convolutions, with excess of fluid. There was a moderate amount of atheromatous degeneration in all the vessels at the base of the brain. No tumour could be seen on the surface. A vertical transverse section through the lower end of the fissure of Rolando cut through a tumour in the right hemisphere the size of a walnut, hard in consistence, in marked contrast to the adjacent brain substance, which was softened, and from which the tumour was marked off by a pretty sharply defined margin. The colour of the section of the new

S., Posterior limb of the fissure of Sylvius. T.S.L., Temporo-sphenoidal lobe. 1 FR., Superior or first frontal convolution. ASC. FR., Ascending frontal convolution. In the temporo-sphenoidal convolutions the grey cortex comes out well, but in the upper part of the section the details are very indistinct, owing to the white softening affecting this part.

growth was on the whole greyish yellow, with numerous small hæmorrhages and many small points of fatty degeneration. On its outer side the tumour involved the cortex for about an inch, at one point, situate about an inch above the lower end of the fissure of Rolando, entirely replacing the grey matter; and the growth was limited to the ascending frontal and parietal convolutions, both of which it invaded at their lower ends. The rest of this section of the right hemisphere showed white softening of the whole centrum ovale, and this change was found to extend forwards as far as the genu of the corpus callosum and backwards as far as half an inch in front of the rostrum. The ventricles were distended with clear fluid, and the ependyma thickened and opaque. The pons, medulla, cerebellum, and cord presented no unnatural appearance. An infarction the size of a Tangerine orange was found on the posterior surface of the lower lobe of the right lung. Both lungs were extremely emphysematous throughout. There was considerable fibroid thickening of the mitral and aortic valves, and in the mitral valve were also some small atheromatous foci. The aorta showed merely slight atheromatous change near the heart. The right auricle and ventricle were greatly distended with black fluid blood, and also contained some rather firmly adherent decolorised clot. The liver and kidneys were much congested. No new growths were discovered on careful searching in any of these organs, nor in the uterus or ovaries; but in the spleen two or three small foci were seen under the capsule. There were some small hard glands above the left clavicle, and along the posterior border of the sterno-mastoid. There was no definite sign of recurrence

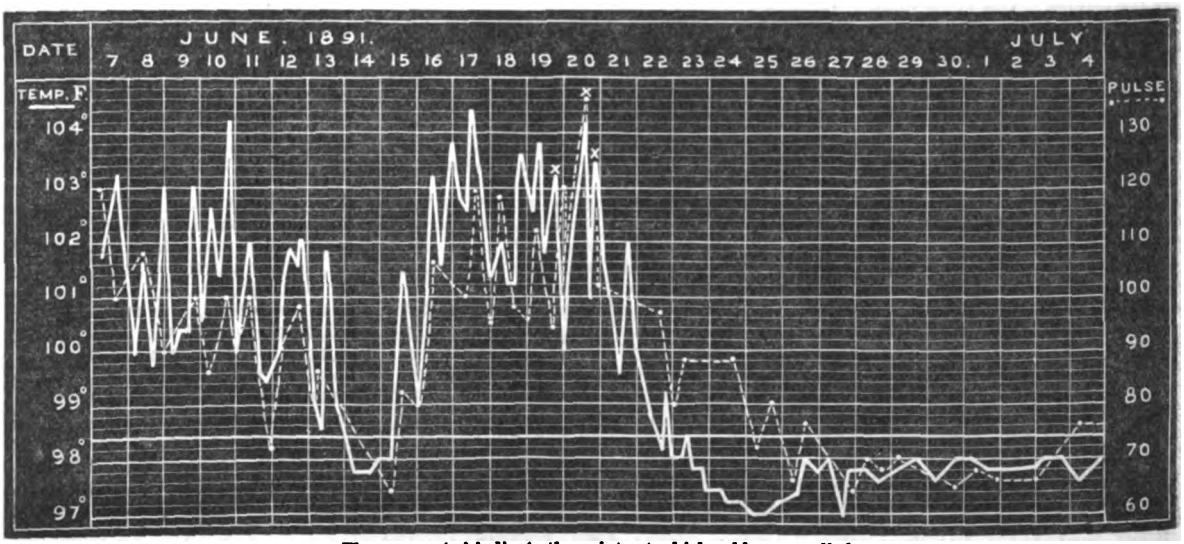
Digitized by Google

in the old operation scar, except just in one part, where there was a little hardening. Under the microscope the cerebral tumour presented the typical appearances of scirrhous carcinoma.

This case is one of very great interest from many different standpoints. In the first place, it would appear that, after all, scirrhus affecting the brain is not a very uncommon affection. Mr. Beadles notes in his communication that in a total of 202 post-mortem examinations in cases of cancer growths in the brain substance were found in four cases, a proportion of 2 per cent.; and doubtless many cases of secondary and some of primary cancer in the brain run their course either with no symptoms at all, or with such indefinite ones that they are not diagnosed before death, and are not found afterwards from want of examination of the cranial cavity and its contents. But where the growth is situated in or near the motor area of the cortex, as in Mr. Beadles' case and the present one, the symptoms thrust themselves upon one, so that even he who runs must read.

Thus in the case now under consideration grave cerebral mischief was indicated at the beginning by epileptiform attacks and gradually increasing hemiplegia. The gradual onset and the distribution of the paralysis, the headache, epileptiform attacks, and double optic neuritis, taken together, indicated that the disease was in the right hemisphere, and that it was in all probability a tumour; while the removal some time previously of a tumour of the breast, and this tumour having been proved to be scirrhus, made it in the highest degree probable that we had to do with scirrhus of the brain. Further still, the mode of onset and spread of the convulsions in the second attack, as described in the history, showed that the irritative lesion at that time bordered closely on the cortical motor centre for the left lower face, which is situated at the lower part of the ascending frontal and parietal convolutions, and the correctness of this indication was beautifully demonstrated at the necropsy. In passing it may be remarked that the occurrence first of a sensory aura (pins and needles), immediately followed by clonic spasm in the same parts, is of interest in connexion with the theory that the motor area of the cortex contains sensory cells. The relation of the case to the surgery of the brain is also of much interest and importance; for if the indications afforded by the history and present state of the patient had been correctly interpreted and acted upon soon after the second fit, there can be little doubt that the tumour could easily and safely have been removed, and thus the patient's life prolonged, and the softening, which would seem to have been secondary to, and probably in some way caused by, the tumour, possibly prevented. Taking all the circumstances of the case into consideration, however, it is quite open to doubt and argument whether this would have been a desirable consummation.

Wolverhampton.



A CASE OF

INFLUENZA PNEUMONIA TREATED BY THE EXTERNAL APPLICATION OF COLD.

BY WM. GORDON, M.A., M.B. CAMB., M.R.C.P.,
PHYSICIAN TO THE DEVON AND EXETER HOSPITAL.

VERY little has been said about cold sponging for the reduction of temperature in influenza pneumonia. Certainly in the dangerous pneumonias occurring in elderly people I am sure the less said about it the better; and, indeed, in many such there is very little temperature to reduce. But I believe there are a few cases in younger patients where life is in peril, largely from the effect of continued high fever, and where it becomes needful to reduce this fever in some way or other. Quinine may fail, as in the instance I am going to relate, and when the choice lies between cold and some depressing drug, such as antipyrin, I should certainly prefer cold. In THE LANCETS of Jan. 31st and Feb. 7th, 1891, Dr. Fenwick's valuable analysis of 1000 cases of ordinary lobar pneumonia demonstrated the advantage of cold in sthenic cases of that disease, and it was chiefly from the perusal of his paper that I felt induced to try the effect of cold in the present instance. This instance is the only one in which I have used it, because no other case coming under my notice has presented what I consider the indications for it—viz., a previously sound patient and a high temperature of sufficient duration and degree to be in itself a source of danger.

Charles W——, aged twenty-eight, an hotel servant, was admitted to the Devon and Exeter Hospital on June 7th, 1891, suffering from pneumonia of the left base. He had been of temperate habits and in good health until attacked by influenza a week previously. In spite of cough and malaise, he remained at work up to the morning of his admission, when he was seized with severe stabbing pain in his left side. When admitted his temperature was 101·8°; pulse 120; respiration 24. There was then little to be detected except fine crepitation over the left lower lobe. Sputum rusty. He complained greatly of pains in the back and limbs, as well as of the pain in the left side. Ten grains of salol were administered for the former, and for the latter a broad piece of strapping was applied round the left half of the chest. This double relief procured him a fair night's sleep. A mixture was given containing quinine, iron, and nux vomica, with some liquor ammoniæ acetatis. During the next few days the physical signs became more developed. There was friction below and outside the left breast, while tubular breathing and bronchophony became marked over the back of the lung. Dulness finally reached as high as the spine of the scapula, accompanied by complete loss of vocal fremitus, weak breath sounds, and ægophony. The heart's apex could not be felt, but the right border of the cardiac dulness extended a quarter of an inch to the

The crosses (×) indicate the points at which cold was applied.

Digitized by Google

right of the right edge of the sternum. On June 12th there was much improvement: the rusty tinge began to leave the sputum, and the physical signs indicated commencing resolution in the lung and absorption of whatever fluid had been poured into the pleura. On the evening of the 13th the temperature was normal, and by the morning of the 15th the patient seemed on the high road to recovery. Towards night, however, the temperature rose again, and on the 16th friction sounds, fine crepitation, tubular breathing, and bronchophony, with dulness, were all present at the right base. At the same time the signs in the left lung began again to extend. On the 18th there were gastric pain and tenderness, with vomiting of everything, and on the night of the 19th violent noisy delirium set in, with a temperature of 103·2°; respiration 40; pulse 120, but regular, slight cyanosis and intense thirst. Except that the pulse remained regular, and that its rate was not excessive for his temperature, he seemed as bad as he could be. The delirium I thought was due partly to the long-continued fever (including the first attack), and partly to the insomnia caused by the fever. So at midnight he was placed under the ice-pail arrangement mentioned by Dr. Fenwick. After an hour the temperature was 101°. The pails were then removed, and a further fall to 100° occurred in the next half hour. The result was a very marked improvement in his condition, the violence of the delirium abating. There was no untoward symptom, no tendency to collapse. In the morning he continued better, but still wandered a little in mind. A dose of chloral (ten grains) and laudanum (ten minims) was then given. He slept several hours, and awoke quite free from delirium, which never returned. Encouraged by this result, directions were given to repeat the cold as often as the temperature reached 103°. This did not occur until the afternoon of the 20th, when the pulse was 136 and the respiration 52. He was sponged all over with tepid water, which was gradually cooled down with ice. Again the temperature fell to 100·4°, with marked improvement, the pulse falling to 118 and the respiration to 40. At 10.30 P.M. the temperature again reached 103°, and again he was sponged. From this time the temperature fell steadily except for evening rises, and was subnormal on and after the 23rd. The pulse and respiration fell more slowly, and the latter did not reach normal, but continued at a rate of twenty-two breaths per minute. (I have observed this same persistent rapidity of breathing in other cases, even with a very low pulse-rate.) On July 15th he went to the seaside almost quite well.

It will be noticed that at no time was there any approach to hyperpyrexia. The cold was used simply to minimise the depressing influence of a pretty steady temperature of 103° to 104°. I do not think the patient could have recovered if we had allowed the fever to maintain its level, and I have no doubt about the very obvious and decided improvement after each application of cold. Every care was taken to avoid unduly prolonging the application, the cold being removed when 101° was reached; also to avoid too rapid cooling.

Exeter.

TWENTY CASES OF FIBRO-MYOMA AND OTHER MORBID CONDITIONS OF THE UTERUS TREATED BY APOSTOLI'S METHOD.[1]

BY J. INGLIS PARSONS, M.D.,
PHYSICIAN TO OUT-PATIENTS, CHELSEA HOSPITAL FOR WOMEN.

ELECTROLYSIS OF ORGANIC TISSUES.

FOR convenience this can be divided into a polar and an interpolar action. As there is considerable difference between them it is necessary to consider them separately. The polar action is distinguished by the collection of acids and bases at the positive and negative poles respectively. It follows, then, that some of the tissues must have been deprived of these bodies, which are thus found in a free state of dissociation. Since this deprivation may be expected to exercise a profound influence on the nutrition of the tissues concerned, it is important to ascertain its origin—whether in fact it takes place from the tissues in contact with the poles or from those lying between them through which the current passes, or from both. Before entering on this question it is necessary to point out that a secondary effect is produced at each pole, by which acid and alkali albumen are formed, and as the accumulation increases a caustic action is developed, which may cause absolute destruction of tissue. This caustic action appears to be most powerful at the positive pole, because the acids are more destructive than the bases. Most observers, including Apostoli, consider either that the poles are equal in this respect or that the excess is on the side of the negative. If the process be watched on the web of a frog's foot under the microscope, there can be no doubt that the positive pole is the more destructive. Extensive coagulation is also seen at this pole, while it is almost absent at the negative.

Coming now to the interpolar action of the current, we find that it is quite different. For instance, there are no free acids or bases to be found, consequently there is no secondary caustic action—in fact, no change can be seen in the frog's foot under the microscope, although we know that something is going on. In the first place a transport of elements occurs. When the acid is separated from its base, one or both of them must cross the intervening space to reach their respective poles. That they do not do this in a free state can be proved by the electrolysis of a solution of iodide of potash, so arranged that there is a solution of starch in the interpolar region but not at the poles. Although iodine is found at the positive and potash at the negative pole, no discolouration of the starch occurs in the interpolar region. The transport of elements appears to exercise a denutritive effect, which in the case of tumours cannot easily be made up again, but which in the healthy tissue is soon recuperated, and, like the effect of moderate physical exercise of the muscles, leads ultimately to increased nutrition. A more important point is to ascertain whether the acids and bases found at the poles are extracted from the tissues in contact with them, or from those in the interpolar region, or from both. In a paper published in March, 1888, I demonstrated by experiments with simple salts that the molecules in the interpolar region were not decomposed by the current, although an exchange of atoms between them took place during the passage of the current. Since then the late Dr. Steavenson demonstrated by experiment that the acid of a simple salt in the interpolar region can be made to give up its base in exchange for another and a different element. The conclusion to be drawn from this is, first, that the current does not deprive the interpolar region of any of its molecules, although it can under certain circumstances alter their composition. The importance of this from a practical point of view can hardly be over-estimated. For instance, if a tumour lies within reach of the electrode we can not only deprive some of its tissues of various acids and bases, but we can also cauterise and destroy some part of its substance; whereas, if it lies in the interpolar region, we can at the most only influence its nutrition by the transport of elements and subsequent polarisation and possibly some osmosis.

Porret's observation that osmosis occurred through a porous partition between certain liquids during the passage of electricity is not of much practical value. It is more than probable that this only occurs to a very limited extent between living cells, because even in the laboratory it is not very manifest unless a strong current is used with badly conducting fluids, conditions which do not often occur in the human body. The same may be said of polarisation. After the passage of a current the human body acts like a secondary battery, and becomes stored with electricity, which is gradually given off in an opposite direction to the original current. It is very doubtful whether this has any therapeutical effect of any importance. I have always found that the quantity of electricity thus disposed of represents but a small fraction of the original current.

FIBRO-MYOMATA.

Electrical Resistance.—When the constant current is applied to the uterus of normal size and position by one electrode intra-uterine and another on the abdominal surface, the direction taken by the current is along the abdominal wall, down the side of the pelvis, across the broad ligaments, and through the walls of the uterus. If the fundus touches the abdominal wall, it then passes directly through. When electricity is applied to a uterine tumour, the current may either pass directly through the abdominal

[1] Paper read before the Obstetrical Society of London, Jan. 6th, 1892.

Digitized by Google

wall to the tumour, or, if the tumour is large and has a high resistance, it may pass along the capsule and not touch the central portion, or, again, it may miss it entirely and go round by the broad ligament. It depends entirely upon the conductivity of the tumour as compared with the tissues surrounding it and the healthy tissues. It is necessary to bear this in mind when giving a prognosis in any case, and much of the success of the treatment will depend on its recognition. I have found by experiment that the fibrous tissue of an old fibroma has a very high resistance, about ten times that of muscle; while the capsule is very often a better conductor than the substance of the tumour. In my own experience it is impossible on this account to produce any effect on fibrous tissue by the interpolar action; the current misses it out entirely, or else passes by the more fluid cells which are in contact with it. Of course it can be destroyed by the caustic action of the poles. The relation of the tumour to the intra-uterine electrode must be taken into account. For instance, if a tumour is submucous and the electrode is brought into direct contact with it, and it alone, the current must of necessity pass through. With an intra-mural tumour we never can be sure that this takes place, and it will only be acted on if its resistance is the same or lower than that of the tissues surrounding it. A large tumour, other things being equal, has a lower resistance than a small one, because the resistance of a conductor is inversely proportional to the area of its cross section. It becomes evident from the foregoing that before we form an opinion in any given case we must consider: (1) the position of the tumour in relation to the cavity of the uterus; (2) its relation to the abdominal wall; (3) its age and consistence, whether hard or soft; (4) its sectional area.

Method of Application.—For the external electrode nothing answers so well as Apostoli clay; although other substances can be used, they are more likely to produce ulceration of the skin. For the internal electrode I have used a copper stem, insulated, and terminating in a platinum end from which the current is given off. The copper stem, on account of its pliability, is very useful when the uterine cavity is distorted and the sound only passes with difficulty.

The results of fourteen cases of fibro-myomata obtained by treatment have been as follows:—

Hæmorrhage.—In all cases this has been arrested or improved. In six cases the subsequent history has been traced out to March, 1891, and up to this date no return of hæmorrhage had occurred. In Cases 1 and 2 a period of over three years has passed without any relapse since the treatment was begun, although in each case the hæmorrhage threatened life, and everything had been tried without avail except abdominal section. Case 6 was not so successful, the hæmorrhage was controlled and kept within bounds as long as the treatment was carried on, but she always relapsed at the end of a month or six weeks if it was discontinued. I advised removal of the appendages, but the patient refused. I heard from her in March, 1891. "You will be pleased to hear that I am better, and do not lose so much." In Cases 13 and 14 only a few applications were made, but even then it was stopped, in one for over a year, and in the other for six months. In three cases—Nos. 5, 9, and 12—it was reduced to a normal amount, but I have not been able to trace out the subsequent history. In quite half the cases there was an increased loss at the commencement of the treatment, but especially with those of a severe type.

Pressure Symptoms.—The relief in this direction was most marked, and I think can only be explained by a diminution in the size of the tumours. It can easily be understood that even a slight shrinkage in the size of a tumour would afford great relief to various structures which had already, to a great extent, accommodated themselves to its presence. This was very marked in Case 13. She was unable to take more than a few short steps at a time, from pressure on the sacral plexus and consequent loss of power over the muscles of the lower extremities. The muscular weakness disappeared after three applications. On the other hand, Case 4, who suffered from pressure on the bladder, showed no improvement after several applications, because it was an unsuitable case. The tumour was ten years old, and probably composed of fibrous tissue alone, which I have shown is almost unaffected by electricity. In contrast to this the bladder symptoms of Case 14 disappeared entirely after eight applications, although the tumour was also ten years old, but then it was much softer, and therefore more amenable to the influence of the current.

Diminution in Size.—That this takes place to a limited extent in most cases no one with practical experience can deny. The amount to expect will depend on the size and consistence of the tumour. An old hard tumour composed of fibrous tissue alone, as in Case 4, remains unaltered, while a soft tumour (Case 11) entirely disappeared. This case is a remarkable one, because the patient became pregnant two years after treatment, showing that it is no bar to conception. This fact might be of the greatest importance if an heir to a title were required. It is evident that removal of the appendages would destroy all possibility of so favourable an issue. In one instance (Case 7) the tumour was removed on account of its size; although electricity had stopped the metrorrhagia and removed the pressure symptoms, the diminution in size was not sufficient. The patient, who was single and had to get her living as a governess, was always open to unkind remarks on account of the size of her abdomen. Dr. Travers successfully performed hysterectomy.

Pain.—If the current be used too strong it is invariably followed by some pain in the abdomen for a day or two following the application; but this soon passes off. Local pains are often relieved after one application. Dysmenorrhœa in suitable cases usually disappears gradually.

Galvano puncture.—Differences of opinion are often expressed upon this point. In properly selected cases it is most useful. At the same time I cannot go as far as Apostoli. He advises that this measure should be resorted to when the blunt electrode cannot be passed, or when a salpingo-ovaritis has not been sufficiently relieved by intra-uterine applications, or when a fluctuating tumour presses into the vagina and demands rapid evacuation. Nothing, to my mind, can be more hazardous than to drive a sharp trocar into a projecting tumour in the uterine canal when we are unable to estimate with precision its position either by touch or sight. His method in this direction appears to me to be faulty. The steel trocar recommended by Apostoli has only a celluloid sheath to protect the vagina. As a consequence, after each puncture a small sinus is left communicating with the vagina, a condition of affairs which is very likely to lead to septic infection, in spite of antiseptic precautions. The trocar which I use has in addition a loose sheath, a second insulation, which does not project above its surface. When a puncture is made this insulating material is in contact with the healthy tissues, while the bare metal lies in the tumour, and the cauterisation is confined to the latter alone. By this means no sinus is left, the seat of puncture is closed in a few hours, and the risk of septic infection is reduced to a minimum. All the punctures were made through the anterior vaginal wall, although Apostoli advises that this should never be done. The tumour lay between the uterus and bladder, and there was no other way of getting at it.

Unsuitable Cases.—Many cases in addition to those described have come under my notice, but they were unsuitable for treatment. Such cases come under the following heads:—1. Old-standing hard tumours, over ten years' duration, causing pressure symptoms without hæmorrhage. 2. The presence of pronounced disease either of the ovaries or tubes associated with, or secondary to, a fibro-myoma. 3. Slow-growing tumours that give rise to no symptoms. 4 Fibro-cystic tumours. Of this class Case 16 is a good example. Several applications were made, but the tumour continued to grow, and abdominal section was finally performed by Dr. Travers. The treatment failed in one case of hæmatocele and two cases of anteflexion with severe dysmenorrhœa. It succeeded in a case of neuralgic dysmenorrhœa and one of primary amenorrhœa.

Conclusions.—Apostoli's treatment is of great value in a large proportion of cases. 1. It stops the growth of the tumour, sometimes reduces its size, and may possibly cause its disappearance. 2 It stops hæmorrhage in most cases. 3. It relieves pain and pressure symptoms. 4. It does not prevent pregnancy.

THE ELECTRIC DOUCHE.

BY W. S. HEDLEY, M.D. EDIN., &c.

AT page 231 of his book on Electro-therapeutics Erb mentions the electric douche. No information, however, is given beyond a reference to a paper by Trautwein. I have not been able to get access to this article, nor am I aware whether the subject has any other literature. It is therefore because it may possibly interest those who are in the same position that I venture to put together the few following points, which are the outcome of an experimental inquiry recently undertaken for my own information. The action of electrised water by means of the electric bath has long been recognised as by far the least painful way of applying the current to the body. But the efficacy of this procedure depends in most cases on a general and distributed action rather than on any strictly localised effects. The electric douche therefore seems to have been devised as a means of retaining the advantages of the electro-hydriatic method and at the same time presenting facilities for strict localisation and accurate dosage, and securing the advantages of a labile as well as a stabile action. The method of application, apart from certain non-essential details, is much of the nature of what would be known in hydrotherapeutics as the "movable jet douche" (douche mobile), and the nozzle is so arranged that the electrised stream escapes in the form of a more or less condensed jet or jets, which, with a certain minimum of pressure, remain unbroken and continuous for a reasonable distance after emerging from the pipe, and therefore for that distance retain their electric conductivity. (Of course there ought to be a means of regulating temperature and pressure.) With this arrangement one pole may be placed in contact with some indifferent part of the patient's body, while the other is connected to the internal metal of the douche, with the result that when the douche is set in action the second pole is brought to the patient by and in the fluid, and may be concentrated as a single jet or distributed as many small jets. The fluid is, in fact, the second electrode.

Let us inquire, then, by direct experiment, how much current this water conductor carries, and how much enters the body of the patient. The following experiments are necessarily only a selected few, but a sufficient number of results are quoted to give some general ideas. Details of the apparatus are also as much as possible omitted. It need only be mentioned that, permanent water pressure not being available, a hand pump drawing from a suitable vessel was used for the douche, which was fitted with a nozzle or rose (having its outer edge insulated with india-rubber) of the size mentioned below. The electric apparatus consisted of a Leclanché battery of seventy-four cells (with a milliampère meter in circuit) and a fair-sized induction coil. One pole was attached to a large electrode on which the patient sat, and the other connected with the metal of the nozzle or rose, well insulated wire being used for the connexions. The following results were obtained:—

TABLE A.

Plain water at 98° F., continuous current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. ¼ in. jet (single).	75	−	1·5 in.	5 milliampères.
2. Do. do.	"	"	0·5 in.	15 milliampères.
3. Rose 2 in. dia., forty-nine perforations.	"	"	1 in.	5 milliamperes.
4. Single jet.	"	+	18 in.	Deflection (taken on reflecting galvanometer) right off scale. Probably quite 100 microampères.

TABLE B.

Salt water (½ lb. to 7 gal.), temperature 98° F., continuous current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. Rose.	75	−	1·5 in.	7·5 milliampères.
2. Single jet.	40	+	18 in.	20 milliampères.

TABLE C.

Plain water, temperature 98° F, alternating current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. Rose.	x	+	1·5 in.	Subject cried out "Stop." Milliampère meter (alternating current) in circuit did not register.
2. Single jet.	"	+	12 in.	Noise marked in telephone. Subject felt current.

Several readings were taken with alternating current and salt water, all showing that the effect was much stronger with salt water than with plain. These experiments seem to show that electricity can be imparted to the human body by means of the electric douche, provided that sufficient electro-motive force be used and the stream of fluid be continuous. Table B shows that when salt water is used strong currents may be passed over considerable distances with a very moderate electro-motive force. Table C shows that by using coil currents, which always possess a comparatively high electro-motive force, as much current as a patient can comfortably bear may be passed over many inches of space. Its current-carrying capacity being thus established, we may glance for a moment at its possible therapeutic effects.

There was a time in the days of "brutal hydrotherapeutic empiricism," when both physician and patient had a (not altogether inexplicable) dread of the "hydrostatic douche." This, however, has given way before a more enlightened method of administration, and the douche is acknowledged to possess stimulating and alterative properties of no mean order. It seems not unreasonable, therefore, to suppose that in the combined electric and hydriatic procedure we may have a therapeutic agent of considerable power. It claims that, according to variations in temperature, force, and duration, it may be resorted to as an agent more gentle and adaptable than even the "electric hand" of the physician, or may be made to become so potent and concentrated as to prove a veritable electro-hydriatic moxa. It presents itself as a means of general electrisation by bringing the various parts of the body successively under its influence; it claims an action that may be strictly localised; and, further, offers itself as a means of producing, through various motor inhibitory and secretory reflexes, those influences on nervous centres and glands which can undoubtedly be brought about by other and more painful methods of peripheral electrical excitation. If it can establish claims of this kind, a field of usefulness seems to lie before it in a class of cases which readily suggest themselves.

Brighton.

AN INQUIRY INTO THE RELATION THAT EXISTS BETWEEN MILD AND SEVERE FORMS OF SOME DISEASES.

BY E. DONALDSON, B.A. T.C.D., L.R.C.P.I., &c.

IN the different departments of science well-marked phenomena lead us to look for or infer the existence of less striking examples of the same or similar phenomena. Prof. Jevons, in his "Principles of Science" (p. 549), writes: "We must regard those changes which we can observe as the comparatively rare aggregates of minuter changes. On a little reflection we must allow that no object known to us remains for two instants of exactly the same temperature. If so, the dimensions of objects must be in a perpetual state of variation." He quotes Prof. Tyndall, as follows: "An upright iron stone influenced by the earth's magnetism becomes a magnet with its bottom a north and its top a south pole. Doubtless, though in an immensely feebler degree, every erect marble statue is a true diamagnet, with its head a north pole and its feet a south pole. The same is certainly true of man as he stands upon the earth's surface, for all the tissues of the human body are diamagnetic." He further illustrates this truth: "The sun's light produces a very quick and perceptible effect upon the photographic plate; in all probability it has a less effect upon a great variety of substances. We may regard every phenomenon as an exaggerated and conspicuous case of a

Digitized by Google

process which is in infinitely numerous cases beyond the means of observation." We find the same truth exemplified in physiology and pathology. Parturition has its minor manifestation in menstruation. Shelley wrote of "Death and his brother Sleep." The "oral whiff" is an exaggeration of the cardio-pneumatic impulses which can be detected in most, if not all, persons. Dr. Hughlings Jackson says: "A fit of epilepsy is an excessive caricature of the normal physiological process during what is called a voluntary action." Mr. Hutchinson has pointed out that rare diseases are sometimes exaggerated forms of what is common. There is a principle which governs the relation between mild and severe forms of some diseases, and which appears not to be recognised in medical writings. The principle is that some well-marked varieties of disease can only occur in communities where less marked varieties are not uncommon If we find in a community rare cases of astigmatism of six dioptres, we are sure to find a large number with less astigmatism. If we find more cases of severe myxœdema in women than men, we may conclude that milder forms of this disease are oftener found in women than men. The functional activity of the thyroid is greater in women. Complexity of function without corresponding complexity of structure practically lowers the level of evolution, and Dr. Hughlings Jackson has taught us that disease frequently first attacks the least organised parts. Hence the fact that women have myxœdema more than men comes under the law of dissolution—the reverse of evolution.

To what diseases does the principle that the worst cases occur amongst those who suffer most frequently apply? It applies to diseases in which inherited predisposition plays an important part—e.g., myxœdema, exophthalmic goitre, Raynaud's disease, &c. It holds good also where there is no marked inherited predisposition, as in myopia. In other cases there is no relationship between frequency and severity. A disease may be equally liable to occur in the two sexes or at any age, but owing to greater exposure to exciting causes one sex or persons of a certain age may suffer oftenest. Infants have purulent ophthalmia less severely than adults, and oftener. If this principle is not recognised error is likely to follow. A physician of great experience writes as follows: "If I may judge from my own experience, these rudimentary cases of Graves' disease are more common in men than in women. Men, as everyone knows, are much less frequently affected with exophthalmic goitre than women, and it would appear (at all events as far as I can judge from my own experience) that when men do become affected with Graves' disease the clinical picture is apt to become imperfect." If the principle I have mentioned applies to exophthalmic goitre, it will be found that women suffer oftener than men from the mild as well as from the severe forms. Von Graefe was probably in error when he said that exophthalmic goitre was more likely to be fatal in men. A distinguished ophthalmic surgeon writes that bad myopia is found oftenest amongst hospital patients, while the benign form is found oftenest amongst private patients. Mr. Priestley Smith has met this by statistics and arrived at a different conclusion—one that is quite in harmony with the principle I am discussing. The question as to the relation that exists between mild and severe myopia is rendered difficult by the fact that some cases of severe myopia differ etiologically from the milder cases. These cases are not, however, sufficiently numerous to vitiate the conclusion that the severest cases occur amongst those who suffer oftenest.

Some difference of opinion exists as to whether mild cases of myopia and albuminuria are to be looked upon as physiological or pathological. It would be well to look on this question in the light of the principle that in communities where the mild forms often occur the severer forms are likely to occasionally crop up. It was thought that albuminuria occurring in association with acute infective diseases was sometimes due to high temperature. It is probable that many of these cases are really mild forms of parenchymatous nephritis due to the different poisons acting on the kidneys.

Londonderry.

LUNACY CASE.—An action against Dr. Littlejohn and Dr. Hay of Edinburgh for £1000 and £500 damages respectively, on the ground that they did "falsely, wickedly, and maliciously swear that the pursuer is a dangerous lunatic," was heard by Sheriff Orphoot in Glasgow on the 18th inst. The pursuer conducted his own case, and, after hearing both sides, the sheriff took the case to avizandum.

ST. MARY'S HOSPITAL.

SOME INTERESTING SKIN CASES.

(Under the care of Mr. MALCOLM MORRIS.)

WE present our readers this week with an interesting series of cases illustrating four of the rarer kinds of cutaneous eruptions. Case 1 is recorded because of the apparent absence of a source of contagion and on account of the rarity of the affection in England. Kral has made some interesting observations with regard to the nature of the fungus in this disease, the result of which he gave to the International Medical Congress in Berlin. Case 2 describes a chronic and obstinate affection, also of unusual character, which ultimately yielded to treatment. Mr. Malcolm Morris, who has had Case 3 under observation since 1878, thinks this undoubtedly a case of Hebra's prurigo from a consideration of the following facts: The relapses of severe eczema, the above attack being an example of the length of time the disease has persisted, the existence of large indurated inguinal and femoral glands, the extreme irritation, the thickening of the skin, and the great depth of the natural furrows. With reference to Case 4, Mr. Malcolm Morris regards this sudden appearance of the erythematous band, separated from the original mischief by healthy tissue, as an additional argument in favour of the essentially erythematous and neurotic character of lupus erythematosus. The patient is a stout and well-nourished woman, who, however, suffers slightly from asthma. For the notes of these cases we are indebted to Mr. L. E. Parkhurst, house physician.

CASE 1. *Favus of the Scalp.*—F. S——, aged ten, was admitted to St. Mary's Hospital on Oct. 20th, 1891. He was sent to the hospital from an inland Somersetshire village. There was no history of exposure to infection or of any source whence infection might have arisen; no cats or canaries in the house. It occurred first when the boy was three months old, and has persisted ever since, growing steadily worse in spite of treatment. No other members of the patient's family have suffered, although he has for years past shared a bed with a younger brother. On admission the head was found to be covered with the characteristic yellow crusts, with mousy odour, extending all over the scalp. The hair was scanty, there was great irritation, and the general health was poor. Hyposulphite of soda fomentations were applied every four hours, and cod-liver oil and iron given internally; subsequently fomentations of resorcin solution. He is still in hospital, but there is marked improvement in every way. The irritation of the scalp early disappeared, and the crusts are all gone. New hair is growing everywhere on the scalp. General health greatly improved.

CASE 2. *Relapsing Pustular Dermatitis of Palms and Soles.*—C. K——, aged fifty, married, was admitted to hospital on Nov. 6th, 1891. There was no history or suspicion of syphilis. She had facial erysipelas eighteen months ago, and when convalescent noticed a breaking of the skin on the soles of the feet, which then discharged a watery fluid; this next attacked the palms. Pustules first appeared twelve months back; they were very painful until pricked, and used to come out in crops, the average duration being about a week. She has not been able to put her feet to the ground for more than a year. She was seen from time to time as an out-patient, but no improvement resulted. She then presented a dry, deeply fissured dermatitis of both palms, with numerous deep-seated pustules over the thenar and hypothenar eminences, about a quarter of an inch square, and containing a thick creamy pus. These are very painful until they are lanced. On the feet there is hypertrophy and thickening of the skin of the soles, with similar deep-seated pustules, but no deep fissures; there are also patches of psoriasis on the knees and elbow; the condition of the palms and soles, however, in no way suggested psoriasis, but was rather of an eczematous character. She was treated at first with a salicylic ointment, and subsequently

Digitized by Google

a weak and then a strong tar ointment. She improved greatly, especially when given biniodide of mercury internally; this is curious, as syphilis is not suspected. She was troubled at first with urticaria, and until the strong tar ointment was used had crops of pustules from time to time. She was discharged on Jan. 15th, 1892, quite well. There were no pustules after the end of November on the hands, but they persisted about a fortnight longer on the feet. She can now stand and walk without pain. The general health has all the time been excellent.

CASE 3. *Hebra's Prurigo.*—A. H——, aged twenty-seven, was admitted to hospital on Dec. 7th, 1891. When three months old a red raised spot appeared on the left cheek, which gradually spread and affected the whole body, save the nose, forehead, lower lip, scalp, and soles of the feet. One of his earliest recollections is the excessive irritation of his skin and the consequent scratching thereby set up, and the itching has continued ever since, but with occasional intervals of slight amelioration. He has suffered severely from asthma and chronic bronchitis for many years. Three months back, and suddenly (after getting heated from some slight labour) the irritation became more than usually severe, and affected the abdomen in the first instance; the skin in this region felt hot, became red, then inflamed, and discharged "a watery matter," and assumed a deep purple colour. On the legs a similar condition followed in a few days, but more gradually; it began to spread up the abdomen, and then appeared in the arms, but independently and not by direct extension. On admission he presented a rough, dry, scaly skin, which was greatly thickened, and had all the natural furrows deepened. On the arms were numerous blood crusts, a multitude of deep fissures, and a discharging eczema; the legs were similarly affected. The front of the lower abdomen was occupied by a deep pigmented—not erythematous—patch of purple colour and irregular but sharply defined outline above, merging into the redness and eczema of the legs below. There was no exudation from the surface of the abdomen, and no papules could be made out owing to the great thickness of the skin. He was suffering from asthma and bronchitis somewhat severely, and had slight fever. He was treated at first by cod-liver oil massage, followed by a mild tar ointment. The skin condition has improved greatly, and the pigmentation over the abdomen has quite gone, but the asthma is worse than ever.

CASE 4. *Lupus Erythematosus.*—E. C——, aged twenty-four, was admitted to hospital on Dec. 10th, 1891. The disease appeared first on the skin of the cheeks (she thinks both about the same time were affected) in 1884, and has been very intractable. She was in hospital in 1887, in 1888, and again in 1891. It has gradually spread, and assumes at present the typical butterfly outline with numerous scars indicating the atrophic stage. There are also on the scalp two dry scaly patches, quite distinct from that on the face, which have also reached the atrophic condition. The interesting feature about the case is that in October last the patient noticed one day that a faint rosy band had appeared outside the old eruption, extending round the chin from temple to temple, and this has gradually darkened, until on admission it presented the appearance of a band of simple erythema one inch wide, and separated by a narrow band of healthy skin from the old eruption, which it in no place joined. This has gradually darkened, and is getting purple, but there is no sign of scarring. Treatment has been directed to the old patch only, and has consisted in cautery (twice applied), followed by a salicylic acid ointment. She has improved greatly.

METROPOLITAN HOSPITAL.

LIGATURE OF THE LINGUAL ARTERY FOR HÆMORRHAGE FROM EPITHELIOMA OF THE TONGUE.

(Under the care of Mr. WALSHAM.)

HÆMORRHAGE in consequence of epithelioma of the tongue ulcerating into the lingual artery is not very common. In this case, owing to the ulcerative chasm being far back in the tongue and the patient being unable to open his mouth widely and protrude that organ, it was difficult to determine the exact source of the hæmorrhage. As the bleeding on admission was very severe perchloride of iron was at once applied to restrain it. This treatment was successful for a time, but on the recurrence of hæmorrhage Mr. Walsham was sent for. The lingual artery was easily found and tied. The hæmorrhage ceased at once, and the wound for exposing the artery healed by the first intention. Mr. Walsham proposed removing the gland and the tongue by Kocher's method, but the patient would not give his consent. The indications for the performance of this operation are mainly four: (1) Before removal of the tongue; (2) for hæmorrhage after removal of the tongue; (3) in cases of malignant growth of the tongue too extensive for removal &c; and (4) in some cases of macroglossia.[1] For the notes of this case we are indebted to Dr. Marshall, senior house surgeon.

John M——, aged fifty-two, was admitted to the hospital on Dec. 11th, 1891, with severe arterial hæmorrhage from the mouth. On examination the tongue was considerably fixed on the right side, and a new growth, apparently epitheliomatous in nature, was found involving the posterior third of the right side of the tongue and the floor of the mouth. The growth was deeply ulcerated, and at one spot a cavity was found passing deeply into the base of the tongue. On the right side of the neck was a mass of indurated and enlarged glands. The hæmorrhage was checked temporarily with perchloride of iron, but in the course of about four hours it recurred to such an extent as to endanger the patient's life. About six hours after admission Mr. Walsham was sent for and ligatured the right lingual artery in the submaxillary triangle. The hæmorrhage, which had stopped, but recurred whilst the patient was on the operating table, immediately ceased.

On Jan. 3rd the patient left the hospital, no further hæmorrhage having occurred since the operation.

SOUTH DEVON HOSPITAL, PLYMOUTH.

CASE OF ATROPHIED KIDNEY, WITH PERINEPHRITIC ABSCESS; NEPHRECTOMY; FÆCAL FISTULA; RECOVERY.

(Under the care of Mr. WHIPPLE.)

THE most likely explanation of this case seems to be the following. Five years ago there was a small calculus in the pelvis of the left kidney. This eventually blocked the ureter, causing atrophy of the kidney, and later on ulcerated through into the descending colon, and was thus got rid of. The present abscess was probably caused by the escape of some intestinal contents into the perinephritic tissues. In removing the kidney, which was adherent to the colon, where the stone had ulcerated through, some damage was done to the wall of the latter, leading to formation of the fæcal fistula. At the operation the escape of fæcal-smelling gas occurred long before the kidney or colon was reached, and certainly was not due to a wound of the colon. For the complete account of this case we are indebted to Mr. W. Gifford Nash, late house surgeon.

M. B——, aged thirty-eight, wife of a marine, was admitted on Aug. 1st, 1891. She stated that she began to suffer pain in the left loin five years ago. At first the attacks of pain occurred at intervals of three or four months, but latterly every three or four days. The pain, which was very severe on the left side of the abdomen, caused vomiting. During the last year the pain had been more constant, and had radiated to the left groin and thigh. For the last three weeks the pain in the thigh and knee had been severe and the thigh had been flexed. Four years ago she had frequency of micturition for six weeks, but latterly had only passed urine twice a day. Two years ago micturition was painful. When admitted she was a well-nourished woman, complaining of pain in the left loin, thigh, and knee. The left thigh was flexed. There was a distinct swelling in the left lumbar region, reaching as low as the crest of the ilium and extending upwards under the ribs. It had a hard rounded border in front, was extremely tender, and apparently fixed. Fluctuation was not obtained. There was no frequency of micturition, and no pain was felt during the act. The urine was acid, sp. gr. 1010, and contained a trace of albumen; under the microscope were seen numerous pus cells, but no crystals, blood, or casts. In two days she passed ninety-eight

[1] Jacobson: The Operations of Surgery, p. 482, second edition.

Digitized by Google

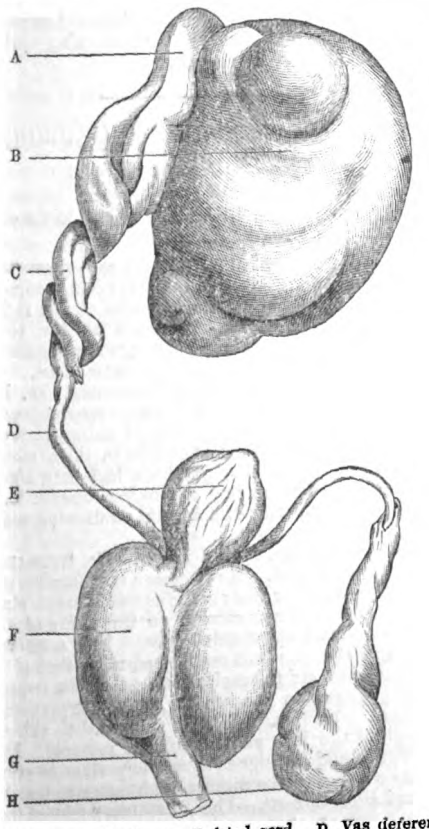
ounces of urine. On Aug. 5th the swelling was explored by the lumbar incision. On cutting through the lumbar aponeurosis and exposing the hard and condensed perinephric fatty tissue there was an escape of gas with a foul fæcal odour. On tearing through the condensed fat, an abscess, containing about three ounces of pus, was opened. The kidney itself was found to be extremely shrunken, and was therefore removed. In doing this it was much torn, as it was intimately adherent to the surrounding tissues. The lumbar muscles were sutured with catgut and the wound closed, except where a drainage-tube was inserted. On Aug. 8th there was a little fæcal discharge from the wound, which continued for a week. The patient, after the operation, immediately lost all the pain in the loin and groin, but a sinus remained until the silk ligature on the pedicle of the kidney came away on Nov. 26th. After this the sinus healed, and the patient was able to leave the hospital on November 30th. The kidney removed was about the size of a testis. The cortical tissue was the seat of chronic interstitial nephritis. There was nothing found to account for the atrophy or the perinephritic abscess.

Medical Societies.

ROYAL MEDICAL & CHIRURGICAL SOCIETY

Antiseptic Preparations of Catgut and Silk.—Torsion of the Spermatic Cord.

AN ordinary meeting was held on Tuesday, Feb. 23rd, Mr. Timothy Holmes, F.R.C.S., President, in the chair.



Mr. W. G. MCPHERSON (Army Medical Staff) supplied a paper on Antiseptic Preparations of Catgut Silk and their relation to Wound Infection (communicated by Mr. A. Bowlby). The author first alluded to the observations of various surgeons on the causation of suppuration in wounds by ligatures supposed to be aseptic, and then described his own experiments. These were conducted in three series: (1) Experiments testing the purity of dry material supplied by surgical instrument makers; (2) experiments testing the purity of material preserved in "antiseptic" solutions; (3) experiments with specially contaminated silk to test the antiseptic value of such solutions. Control experiments were also made. A description was then given of the preparation of the silk used for surgical purposes, and it was pointed out that in its manufacture it was subjected to various processes which were well calculated to destroy any organisms it might contain, although this was not the object directly in view. The various experiments and their results were then given in detail, and attention was particularly directed to the results obtained with different kinds of material, the object of the writer being to ascertain the most reliable material for ordinary surgical use, and the best means for preserving it in an efficient condition. The following conclusions are then drawn:—(1) All so-called "antiseptic" preparations must be received with considerable caution, and there is good reason for rejecting such preparations of catgut; (2) asepsis can with certainty be obtained by the cheapest, simplest, and most efficient means of all—namely, by boiling or steaming; (3) material thus rendered aseptic may be readily kept aseptic in bottles containing no solutions of any kind; (4) the methods of keeping ligature material aseptic by means of solutions, as suggested from time to time by various surgeons, are unnecessary; (5) the most aseptic material sold by surgical instrument makers is probably the fine undyed silk twist, untreated by any antiseptic material.—The PRESIDENT said he had never experienced any ill effects from the use of catgut for ligatures and sutures.—Mr. HOWARD MARSH mentioned a case in which he had amputated through the thigh. He had used catgut, carbolised and sent direct from the instrument makers', for his deep ligatures. In spite of every care at the time of the operation, within forty-eight hours the wound became foul along the tracks of the sutures and ligatures, and the case finally terminated fatally. In his own mind there was no doubt that this was due to a septic condition of the catgut and of the carbolic preservative fluid. At St. Bartholomew's Hospital there was a profound mistrust of material obtained from the instrument makers' for ligatures, and no house surgeon would think of allowing anything to be used which he had not himself prepared. When properly prepared he thought that there was no particular difference in this respect between silk and catgut, though he himself preferred silk.—Mr. BARWELL referred to a paper of his on tying arteries in their continuity, which he had formerly read before this Society, in which he had quoted from a work on the preparation of catgut how that the intestine was first partly macerated for the removal of everything except the muscular coats, and that the muscular coats still containing putrefactive organisms became converted into catgut, and without further sterilisation were stored in carbolised oil, which was known not to be a sufficiently powerful germicide for their destruction. He kept his materials for sutures and ligatures in solutions of perchloride of mercury or of carbolic acid for long periods before using them.—Mr. BRUCE CLARKE had for several years given up catgut kept in carbolised oil for silk rendered aseptic by boiling. He described the form of bottle in use at St. Bartholomew's Hospital for storing ligatures. These bottles were ordinarily kept corked, and were filled with some antiseptic solution. During use the cork was removed, and a rubber cap which was kept in the antiseptic solution in the bottle was stretched over its mouth and the ligatures drawn out through it.—Mr. STANLEY BOYD referred to the work that had been done on the Continent on this subject, by which catgut kept in carbolic oil had been for some time condemned. He mentioned Volkmann's case, in which a patient died of anthrax, produced by a catgut ligature, which had originally been made from the intestines of a sheep which had died of anthrax. He believed that it was important that the material used should be non-absorbent, and he used silkworm-gut for deep sutures and horse-hair for superficial ones, and found both very satisfactory.—Mr. GOLDING BIRD agreed with Mr. Boyd that the texture of the substance used was of great importance. Those substances which were least liable to be digested—such as silk-worm gut, silk, or wire—were the best.—Mr. WATSON CHEYNE agreed with the general feeling which had been expressed as to the unreliability of the materials as they were supplied by the makers, and said that he should never think of using anything which he had not himself rendered aseptic. He had not experienced much suppuration from the use of catgut sutures or ligatures, though they might contain putrefactive bacilli, as Mr. Barwell had stated, which were not destroyed by after treatment with carbolic oil. It was probable, however, that micrococci rather than bacilli were most injurious to wounds. At King's College Hospital the materials, as obtained from the makers, were loosely reeled and rendered aseptic by immersion in strong carbolic solution (one in twenty). He agreed with the first three conclusions of the author; but with the fourth, though perhaps unnecessary for experienced bacteriologists, who were aware of the many sources of contamination, yet for others he thought that it would be safest for them to use some antiseptic solution in which to keep their sutures and ligatures.—Mr. HEYWOOD SMITH thought that silkworm gut was the best material for sutures.—Mr. BOWLBY, on behalf of the author, stated that one reason why he had recommended that ligatures should be preserved in a dry state was that they were then somewhat less liable to be a source of bacterial infection, as it was well established that organisms required some moisture for their development. In the paper silkworm gut had not been referred to, as it was unsuitable for ligatures on account of its stiffness.

Mr. THOMAS BRYANT communicated a paper on Torsion of the Spermatic Cord, with Strangulation of the Testicle. The author recorded a case of this hitherto unrecognised affection, which occurred in a boy aged fifteen, with an imperfectly descended testicle, and which he saw in consultation with Dr. Fox of Barnet, in September, 1889. The case in many points simulated one of strangulated hernia; indeed, it was at first so diagnosed. In an exploratory operation undertaken for its relief its true nature was at once revealed, when an imperfectly descended testicle, black from venous congestion brought about by complete torsion of the cord, was exposed. Three half-twists made inwards completely untwisted the cord, and an attempt was made to save the testicle, as it was quite warm. The wound healed kindly after the operation, but the testicle wasted. A good recovery ensued. When this case first occurred it was thought to have been unique, but in the summer of 1891 a preparation was forwarded by Mr. G. Nash, of the South Devon Hospital, to the Royal College of Surgeons

Digitized by Google

for examination, which was clearly of the same kind. This case is therefore fully quoted by the author, with the account of the preparation as given by Mr. Targett, the Pathological Curator to the College. In both of the cases brought forward the twisting of the cord took place in boys; in both the accident affected the left side, and in both there was an incomplete descent of the affected testicle. In the author's case the torsion took place within the inguinal canal; in Mr. Nash's case it was reported to have occurred in the external ring. No explanation of the process by which the torsion of the cord was brought about is attempted, for the author states that neither accident, nor any of the changes which take place in the organ during its physiological descent, seem capable of helping us towards a solution of the problem. That cases similar to the two now published have occurred before the author has no doubt, and he is equally sure that such cases have been described amongst those of inflammation of an ectopic testicle. He believed that one such has been published by Mr. Jacobson (p. 471 in vol. iii. of Mr. Holmes's last edition of his "System of Surgery"). He also maintained that if his own case had not been operated upon, its true nature would never have been recognised; and if it had been allowed to run its natural course, it would probably have been described as one of gangrene or disorganisation of the testicle from acute inflammation. He was disposed to think that many of the cases of atrophy of the testicle which has taken place after a supposed inflammation coming on without any clear cause are of this nature, the strangulation of the cord in such cases being less severe. As an appendix to the paper the author gave a case of the same kind, which was reported to him by Dr. W. Keen, of Philadelphia, United States, and which in every way supports the views put forward by the author.

The Secretary then read a communication from Mr. BLAND SUTTON describing a specimen of Axial Rotation of the Testis in an old pug dog, and the specimen was exhibited. In it the cord of the right testicle (which contained a large tumour) had

A, Epididymis. B, Testis. C, Twisted cord. D, Vas deferens. E, Bladder. F, Prostate. G, Penis. H, Testes in sac.

rotated two and a half times, the disposition of the organs being shown in the accompanying figure. Cases similar to those of Mr. Bryant had been described by Nicoladoni and Cohen in Germany, and abstracts are furnished by Bramann in Langenbeck's Archives, vol. xl.—Mr. W. [G. SPENCER showed a specimen which had already been recently exhibited by him at the Pathological Society, which, though somewhat resembling, was not really similar to Mr. Bryant's cases.—Mr. HULKE asked if in Mr. Bryant's cases there had been long mesorchia. He referred to a paper which he had read before this Society in 1866, in which he had described large sacs in the scrotum, in which the testes had floated in and out of the peritoneal cavity, suspended by long mesorchia.—Dr. HERBERT SPENCER referred to Mr. W. G. Spencer's specimen, and asked Mr. Bryant if at the time of the operation in his case he had noticed any band. He was of opinion that extravasated blood at the time of birth sometimes prevented the descent of the testes into the scrotum, and that a band sometimes remained in after life as a sign of this extravasation.—Mr. BRYANT, in reply to Mr. Hulke, said that in this case the testicle was only just showing through the external abdominal ring, and that there was a long mesorchium; in reply to Dr. Spencer, he said the testicle was rotated one and a half times, and there was no sign of any band.

MEDICAL SOCIETY OF LONDON.

Arthrectomy.—Epithelioma of Tongue.—Old Dislocation of Shoulder treated by Operation.—Floating Spleen.—Friedreich's Disease.

A "CLINICAL EVENING" of this Society was held on Feb. 22nd, the Vice-President, Mr. Reginald Harrison, in the chair.

Mr. CLUTTON exhibited three cases in which he had performed Arthrectomy by a new method for the relief of tubercular disease of the elbow-joint in children. During 1888 four such cases were submitted to operation at the Victoria Hospital for Children, one of which had eluded search, though when last seen the result was quite equal to that in those shown. The operation consisted in opening the joint by dividing the olecranon and removing all the diseased structures with a sharp spoon and scissors. The parts were reunited and kept absolutely at rest. No passive movement was at any time performed, and a plaster-of-Paris splint was continued for three or four months. The range of movement now present was obtained entirely by the patients themselves. The results were seen to be but little short of the normal. If the cartilages at the time of operation were firmly fixed to the bone beneath and the wound kept aseptic, the joint would not ankylose, even though it be kept at rest for some months; whereas if the cartilages be detached and a movable articulation be required, the ends of the bones must be removed as in the ordinary method of excision.

Mr. BRUCE CLARKE exhibited a case of Epithelioma of the Tongue which had been seen in the gummatous stage, but, the patient having absented himself for many months, the disease was now too far advanced for operative interference. He proposed to inject a solution of aniline dye with a view of exhibiting the effect to the Society on some future occasion.—Mr. MARMADUKE SHEILD mentioned a case in which he had injected pyoktanin into a malignant growth without obvious effect. He remarked that the development of the growth in the centre of the tongue, as in the case exhibited, was unusual, though he could recall two others.—Mr. WATSON CHEYNE alluded to three cases of malignant disease, two being sarcoma, so treated, in which no improvement resulted. In one diffuse suppuration occurred in the neck after injection by the mouth.

Dr. SIDNEY PHILLIPS showed a man affected with Acromegaly who had attended among his out-patients for sciatica. So far as could be gathered from the history, the patient being unaware of the condition himself, its duration had been five years. There was very marked hypertrophy of the feet and hands, the nails were flattened, longitudinally striated and cracked, the face exhibited considerable enlargement of the lower jaw, with thickening of the cartilages of the nose and of the outer edge of the orbits, the lower lip, tongue, and tonsils were hypertrophied, and several teeth had fallen out. The pelvic bones were enlarged, there was an increase of the dorsal and lumbar curves of the spine, and the ribs were thickened. The thyroid gland was not to be felt, and appeared atrophied. There was some high-pitched resonance over the manubrium sterni. On the back was a pedunculated molluscum fibrosum, such as had been noticed in previous cases. The man suffered from headache

Digitized by Google

and profuse sweats. Sight was failing, owing possibly to the presence of choriditis, which had been observed. The thigh and leg on the side affected by sciatica were wasted. There was no great increase of appetite and no loss of taste, such as had been described. An unusual feature in the case was an extension of the enlargement to the forearms.—Mr. TAYLOR inquired as to the affection of the fields of vision in relation to the possible presence of an enlarged pituitary body pressing on the optic tract.—Mr. MARMADUKE SHEILD asked for information relative to the mode of enlargement of bones.—In reply, Dr. PHILLIPS said there was no limitation of fields, and that he was unaware that any minute examination had been made of the bones in these cases. There was thickening, but no elongation.

Mr. PEARCE GOULD exhibited a case in which he had operated for Old Unreduced Dislocation of the Shoulder. There had been paralysis and some wasting, with great pain in the limb, from pressure on the nerves. An attempt at reduction under chloroform having proved unsuccessful, on April 5th, 1890, he had made an incision as for excision of the head of the humerus, and, having divided all the muscles in connexion with the great tuberosity, managed to replace the bone. Although the humerus had been dislocated two months, there was now practically as good movement as in the healthy limb. Many of the paralysed and wasted muscles had recovered, and there only remained some defect in those supplied by the ulnar nerve, which had been most profoundly injured.

Mr. WATSON CHEYNE showed a second case of the same sort, but in which four months had elapsed between the dislocation of the bone and its restoration, the man, in addition, having failed to attend the hospital subsequently. In consequence of this and of having had to divide all the muscles with the exception of part of the pectoralis major, as well as to clear out the glenoid cavity, range and power of movement were somewhat defective, and the head of the bone had slipped slightly forward.—The VICE-PRESIDENT referred to the history of these cases, and the improvement introduced by this method of treatment.—Mr. MARMADUKE SHEILD, referring to his own paper at the Medico-Chirurgical Society, deprecated the application of great force in attempts at reduction. Excision, he thought, was easier and preferable in cases of long standing. The results were very satisfactory. Where there was fair movement and no trouble from pressure on nerves it was better not to interfere.—Dr. SOLOMON SMITH inquired as to the cause of difficulty in replacement after the muscles were divided freely, and whether in the second case there was any chipping of the glenoid rim to account for the bone subsequently falling forward.—Mr. PEARCE GOULD referred the difficulty in reduction to the great shortening and tension of muscles, fasciæ, and ligaments. He advised that when replacement was called for one good effort should be made under chloroform, and if this failed, operation should be proceeded with. He agreed entirely with the remarks of Mr. Sheild. — Mr. WATSON CHEYNE referred to the danger, in using force, of rupturing the axillary artery. He had observed no chipping of the glenoid fossa during his operation.

Dr. LESLIE OGILVIE showed two cases of Floating Spleen, occurring in two boys in the same family. Both had suffered from rickets. The elder one was able to depress and protrude the organ, as a tumour, by voluntary effort.—Sir HUGH BEEVOR mentioned a case previously shown, where there was great laxity of the abdominal wall on both sides.

Dr. JAMES TAYLOR demonstrated a case of Friedreich's Ataxy in a boy. There were choreic tremors, marked ataxy, nystagmus, and cramps in the legs. There was some degree of lateral curvature, thermal impressions were delayed, and knee-jerks were lost. The disorder had come on six months after recovery from diphtheritic paralysis. An elder brother was rather worse, the third, a girl, being unaffected. The boy exhibited the "humped foot" (talipes equino-varus) usually met with in this disease. Replying to Mr. Clutton and Dr. Ormerod, he could not say when the foot deformity occurred. There was no history of alcohol, syphilis, or neurosis.

HARVEIAN SOCIETY OF LONDON.

A MEETING of this Society was held on Feb. 4th, Dr. W. B. Cheadle, President, F.R.C.P., in the chair.

Senile Tuberculosis. — Mr. HOWARD MARSH read a paper on Senile Tuberculosis, a title which, in view of recent advances of pathology, he had ventured to substitute for that of Senile Scrofula, originally used by Sir James Paget. He thought all cases occurring in patients over fifty should be regarded as senile. This limit as to age was an arbitrary one, but it was clinically sound. The case was related of a man of sixty-three, who had tubercular disease of his knee, going on to suppuration, and who had somewhat advanced phthisis of both lungs. Amputation was performed, and rapid healing of the wound was followed by marked improvement of the general health. A tubercular knee-joint was also shown from a lady of sixty-seven, in whom Mr. Thomas Smith had performed amputation, and who made a very favourable recovery. Particulars of four cases of senile tuberculosis of the hip-joint were given, in two of which the patients had phthisis; while a third, a patient under the care of Mr. Langton, died of general tuberculosis attended with symptoms of tubercular meningitis. The author described four cases of caries of the spine in the old—one of them having been under Mr. Butlin,—two cases of tuberculosis of the wrist, and two of the testis. In the great majority of the cases related suppuration had occurred. Mr. Marsh discussed the diagnosis (which was often very obscure in the early stage) between senile tuberculosis and osteo-arthritis, and between the former and malignant disease in cases in which the lymphatic glands were the parts affected. Senile tuberculosis showed, he remarked, a strong tendency to suppuration, and was often inveterate. In some cases, however, sound repair had occurred. Treatment must, as in younger subjects, aim at improvement of the general health; local rest must be secured, and matter must be evacuated, aseptically, as soon as it was detected. In many instances, amputation became necessary, and in the majority of cases this was well borne; the wound healed favourably, and often very quickly.—The PRESIDENT remarked upon the similarity between tuberculosis of the young and of the aged.—Mr. D'ARCY POWER thought that in the aged the tendency was to necrosis rather than caries.—Dr. WILLIAM HILL referred to cases of senile tuberculosis of the larynx.—Dr. Drew, Mr. Cripps Lawrence, Dr. Winslow Hall, and Dr. Sutherland also spoke.—Mr. HOWARD MARSH briefly replied.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

WEDNESDAY, JAN. 20TH.

Mr. ANDERSON, F.R.C.S., President, in the chair.

Chorea.—Dr. HANDFORD showed a case of general chorea in a woman aged sixty-three, following left hemiplegia, but presenting the characteristics of senile chorea rather than of post hemiplegic chorea, inasmuch as the movements affected equally the face and both upper extremities, and to a much slighter extent both lower extremities. The prognosis as to cure was not very favourable. Dr. Handford also showed a man aged fifty in whom progressive muscular atrophy, with marked symptoms of bulbar paralysis, had followed an attack of left hemiplegia three months previously. The hemiplegic paralysis had been almost completely recovered from, but the bulbar disease had caused complete aphasia, with difficulty of swallowing and attacks of dyspnœa.

Nasal Cavities and their Diseases.—Dr. STEWART read a paper on this subject. He discussed the diagnosis in cases of suppuration of one or other of the accessory cavities in relation with the nose, and commented on the rarity of disease in the frontal and sphenoidal cells. The most important function of the nose was considered to be that of allowing free passage of air in respiration; hence the importance of removing spurs on the septum, polypi, hypertrophies, and post-nasal adenoma. Where suppuration existed along with polypi the last should be first removed. In chronic pharyngitis and laryngitis it was important to examine the nose, as a cause of the disease might often be found there.

Nasal Hydrorrhœa.—The PRESIDENT related the case of a young woman aged nineteen who had for some time been troubled with a perfectly clear, watery discharge from the left nostril. The discharge was almost continuous, but could be increased by inclination of the head to the opposite side, and after a quantity had flowed forth in this way it would for a time cease. There was no symptom or sign of disease in either the ethmoidal, frontal, or sphenoidal

Digitized by Google

sinuses, and no tumefaction of the cheek or other sign of distension of the antrum. Nothing could be discovered in the anterior or posterior nares. From the symptoms it appeared evident that the antrum furnished the discharge. The molar teeth on the affected side were carious, and the cavity was opened by extracting the second and perforating the bone, when a quantity of clear fluid similar to that discharged from the nose was evacuated. The cavity was drained into the mouth, and douched daily with an astringent wash. This did not effect a cure, so the opening in the bone was enlarged to a sufficient extent to admit the end of the little finger, when a number of minute polypi were found projecting from the mucous lining of the antrum. The interior was scraped with a director and swabbed out with a solution of chloride of zinc, which effected a cure in about six weeks. When last seen, some months after, the patient was quite well, and had no recurrence of the symptoms. Allusion was made to a case very similar to the above in many respects which had been reported by Sir James Paget to the Clinical Society in 1879.

Specimens.—Dr. HANDFORD showed Transverse and Longitudinal Sections of Hardened Brains affected by Tumours, also photographs illustrating Ocular Paralysis and Cerebral Tumours. Mr. CLEMONS, for Dr. Handford: Microscopic Section of Sarcoma of Brain.

Reviews and Notices of Books.

Text book of the Eruptive and Continued Fevers. By JOHN WILLIAM MOORE, B.A., M.D., M.Ch. Univ. Dub., Fellow and Registrar of the Royal College of Physicians of Ireland; Physician to the Meath Hospital, Dublin; Joint Professor of the Practice of Medicine in the Schools of Surgery of the Royal College of Surgeons in Ireland; Consulting Physician to the Cork Fever Hospital, Dublin, &c. Dublin: Fannin and Co. 1892.

THE author of this text-book in his preface briefly alludes to the circumstances under which it has been published. He modestly disclaims all intention of competing, as it were, with such a work as Murchison's monograph on the Continued Fevers, the last edition of which was edited with so much ability by Dr. William Cayley. As regards the eruptive fevers, however, he points out that we possess no work at all analogous to, or comparable with, that of Murchison on the Continued Fevers, notwithstanding that a full and accurate description of these diseases is to be found in the third edition of Hilton Fagge's and Pye-Smith's Text-book of the Principles and Practice of Medicine, and in other standard works. It has been the author's endeavour, he tells us, to gather into a focus the most recent views on the etiology, bacteriology, symptoms, pathology, and treatment of this eruptive fever group of diseases. Dr. Moore alludes to the honourable position which the Irish universities, licensing bodies, and schools have occupied in recognising the great practical importance of a knowledge of this subject, and in insisting upon evidence being furnished by medical candidates of a personal clinical study of fever.

In opening a new medical text-book we naturally ask ourselves not only whether its author has anything to say and knows how to say it, but whether he possesses the requisite knowledge and experience to qualify him for the work. As regards Dr. Moore's qualifications in the latter respect, we may remark that he adverts to the advantages he gained from the teaching of Stokes and Hudson, and to the fact that for thirteen years he was one of the physicians in the Cork-street Fever Hospital, Dublin.

Part I. forms the introduction, in which such subjects are considered as the intimate nature of fever, the intimate nature of contagion, micro-parasitic diseases, and the general principles of treatment of the eruptive and continued fevers under the heads of "Preventive Treatment or Prophylaxis" and "Curative Treatment." These subjects occupy five chapters. Part II. deals with the exanthemata or eruptive fevers in eighteen chapters; and Part III. with the continued fevers, to which twenty-six chapters are devoted. In the chapters forming the introductory part of the book the reader is first of all furnished with a carefully written *précis* of the latest theories of animal heat, of investigations into the nature and causes of pyrexia, the pathology of the infective or specific fevers, and an explanation is given of the essential phenomena of fever. In regard to the thirst of fever, we are glad to notice that Dr. Moore dwells strongly upon a practical point, which, however obvious, is occasionally neglected—viz., the great importance and value of cold water as a beverage. The first chapter closes with some sensible remarks on how water may be supplied to the fever patient, the importance of cold water as a beverage in washing out the retained products of tissue change, and the absence of risk to the patient of frequent ablutions necessary for the maintenance of personal cleanliness. Chapters 2 and 3 deal with the intimate nature of contagion and the germ theory of disease and micro-parasitic diseases. The author summarises the latest views of various authorities on these subjects, including Metchnikoff's theory of phagocytosis and its results, gives a classification of micro-parasitic febrile diseases, exclusive of septicæmia, with observations on the behaviour of the temperature and the cyclical course of specific fevers, and adds a useful table embodying information as to the periods of incubation, invasion, eruption, mode of defervescence, duration of fever, form of desquamation, time of quarantine and isolation for the group of eruptive fevers and continued fevers respectively. In Chapter 4, under the head of "Preventive Treatment," we have some general remarks on disinfection and disinfectants, the general plan of disinfection laid down by Dr. Emerson Reynolds, F.R.S., Professor of Chemistry in the University of Dublin, with that observer's latest investigations on a new and powerful disinfectant named thiocamf. Then follows a brief account of the official regulations for disinfection adopted in Berlin, and reference to a paper read in the Section of Bacteriology at the late International Congress of Hygiene and Demography in London by Stabsarzt Dr. Behring of Berlin, together with information relating to hygiene, recent legislative sanitary enactments, and public health provisions generally. Under the head of "Curative Treatment" the author has a practical chapter in which he deals with the general principles of treatment of fevers, and passes in review the various agents that have been used or recommended for the purpose.

After a brief preliminary chapter of general nature, Dr. Moore next proceeds to a consideration of the various exanthemata, and begins with small-pox. Diagrams, copied from the annual summary of births and deaths of the Registrar-General for England, are inserted throughout the volume in regard to this and other fevers, to show the weekly departure from the average weekly number of deaths. The bacteriology of small-pox is still incomplete. A long experience in the wards of the Cork street Fever Hospital, Dublin, has led him to the conclusion that a purpuric or hæmorrhagic tendency early in small-pox postpones—it may be indefinitely—the appearance of the true variolous eruption. It is sometimes difficult to differentiate between a case of this grave variety of the disease and one of purpuric fever or epidemic cerebro-spinal meningitis.

We may here say that the text-book is well illustrated with charts of the temperature ranges of small-pox and of the other fevers, eruptive and continued, and that, with three exceptions, they have been reproduced from charts taken

Digitized by Google

from the author's hospital practice. The influence of vaccination is carefully considered and set forth in tabular form. The use of the warm-bath treatment in bad small-pox is dwelt upon and illustrated by the graphic description of a case. Chicken-pox, measles, scarlatina, rötheln, and erysipelas follow the chapters on small-pox. In the description of these diseases, and, indeed, throughout his book, the author has of course drawn largely from different well-known authorities. It could not be otherwise in the case of a text-book which is necessarily in great part a compilation; but Dr. Moore expresses his own opinion, relies on the results of his own experience, and introduces comments and criticisms derived from his own observations and reasoning wherever necessary. The latest and soundest information is afforded in regard to the etiology, pathology, clinical history, and treatment of this group of diseases.

Part III. is the concluding portion of the work, and deals with the continued fevers. The order in which these are taken is simple fever, typhus fever, relapsing fever, and typhoid or enteric fever. Our knowledge of the exact nature, causes, and varieties of simple continued fever has not advanced much, and there is, speaking generally, a lack of precision in regard to it. The chapters on typhus fever embody a large amount of information drawn from the best available sources. We cannot yet be said to have acquired any definite knowledge of the bacteriology of typhus fever. Dr. Cayley expresses a general conviction when he says that, judging from analogy with relapsing fever and other contagious diseases, it seems probable that typhus fever is due to a specific microbe which requires conditions of overcrowding and imperfect ventilation to develop its virulent and contagious properties. We have no doubt ascertained a number of interesting and important facts respecting the typhus poison. It is, as everyone knows, an eminently infectious disease, and the contagium may remain latent for long periods. Alluding to Haller's observation that the contagium of typhus fever is lighter than atmospheric air, and that the disease has spread to the upper storeys of a hospital when it was treated on the ground floor, whereas the patients in the lower storeys enjoyed perfect immunity when the typhus fever patients were treated above, the author cites the practice adopted at the Meath Hospital a quarter of a century ago in evidence of the correctness of this observation. Relapsing, famine, or spirillum fever is next considered, and the historical sketch, bacteriology, clinical description, pathology, and treatment of the disease are briefly but well set forth. Dr. Moore states that he has never seen a case of the disease in his hospital or private practice, and he consequently disputes the accuracy of Hirsch's unqualified statement, to the effect that the disease is endemic in Ireland. The concluding part of the volume, with the exception of a short final chapter on infection and immunity, is taken up with a comprehensive consideration of enteric or typhoid fever. The bacteriology is fully considered, the investigations of Gaffky, Eberth, Koch, Klein, and a number of other authorities being referred to. Dr. Moore says that his opinions have necessarily been modified by the discovery of Eberth's bacillus typhosus. He now holds the doctrine that enteric fever arises only when the specific microbe enters the body, and especially the intestinal canal, of a susceptible individual. He traces out the probable way in which enteric fever arises in connexion with the discharge of these micro-organisms, as resting spores, into faulty drains or into the ground, there to await suitable temperature and nourishment until they gain entrance into a susceptible body, develop into bacilli, and begin anew their cycle of existence as pathogenic microbes. The various paths of infection are then traced out. He has some interesting remarks on the close correlation that exists between enteric fever and that variety of pneumonic fever to which the term pythogenic pneumonia has been applied. The results of our own experience are corroborative of this. We think that the period of incubation of enteric fever is often prolonged beyond two weeks. The author mentions that of late years the insidious onset of enteric fever has given place to a more abrupt and vehement advance and rapid rise of temperature—at least that has been his experience in Dublin. Attention is directed, in connexion with the nervous system, to Dr. Angel Money's paper on reflex actions, knee-jerks, and muscular irritability in typhoid fever, phthisis, and other continuous fevers, which appeared in THE LANCET of Nov. 7th, 1885. Relapse in enteric fever is fully considered, and illustrative instances are given. A relapse may occur, by the way, after longer intervals than commonly laid down. The author agrees with Dr. Hilton Fagge that there are rare instances of typhoid fever in which the intestinal glands are not affected, and alludes to cases recorded by Dr. Sidney Phillips, himself, and others. The question of laparotomy is fully considered in connexion with perforation in enteric fever. We think that Dr. Cayley, in his article on Typhoid Fever in Dr. Kingston Fowler's Dictionary of Practical Medicine, has put this subject shortly and well.

In a book containing so much and such a variety of information it is embarrassing to know what to select for notice, and we need scarcely add that there are a number of subjects which we should gladly have touched upon, but our space is already exhausted. This text-book of the eruptive and continued fevers is, in our opinion, a learned and able work. A reference to the index of names will show the large number of authorities which its author has consulted and quoted, and be sufficient evidence of the laborious nature of his undertaking. The work is clearly written, and has merits which will commend it to the profession.

OUR LIBRARY TABLE.
